Networks consists of a large, but finite, number of nodes connected by links. In the modern world, networks are ubiquitous:

- social and communication networks,
- world wide web and internet,
- scientific and other collaboration graphs, ...

Preferential attachment is a principle that aims to explain the emergent features of these networks. It was made popular by Barabási and Albert (1999).

Networks are built dynamically by adding vertices one-by-one. When a new vertex is introduced, it is linked by edges to a fixed or random number of existing vertices with a probability proportional to an increasing function f of their degree. The higher the degree of a vertex, the more likely it is to establish further links.

We get a first criterion for the existence and size of a giant component.

《日》 《圖》 《臣》 《臣》

= nar

We get a first criterion for the existence and size of a giant component.

Proposition

The proportion of vertices in the largest component of the network converges to the survival probability p(f) of the killed branching random walk, while the proportion of vertices in the second largest component converges to zero, in probability.

In particular, there exists a giant component if and only if the killed branching random walk is supercritical, i.e. p(f) > 0.

《日》 《圖》 《臣》 《臣》

Size of the giant component

Relative size of giant component

Simulation for the linear case $f(k) = \gamma k + \beta$.

Framework of the proof

- We couple the neighbourhood of a uniformly chosen vertex with the genealogy of a killed branching random walk. This coupling is successful with high probability if up to log N vertices are explored.
- A sprinkling argument is used to establish the existence of a giant component from the local information. This means that we consider the approximating trees for a network with a slightly reduced edge density. If they survive percolation with positive probability, the remaining edges will connect the surviving trees with high probability, and hence a giant component exists.

- We couple the neighbourhood of a uniformly chosen vertex with the genealogy of a killed branching random walk. This coupling is successful with high probability if up to log *N* vertices are explored.
- A sprinkling argument is used to establish the existence of a giant component from the local information. This means that we consider the approximating trees for a network with a slightly reduced edge density. If they survive percolation with positive probability, the remaining edges will connect the surviving trees with high probability, and hence a giant component exists.
- The underlying branching random walk has infinite offspring and a uncountable but compact typespace. Martingale arguments are used to show that the killed branching random walk survives percolation if 1/p is strictly smaller than the largest eigenvalue of an associated score operator. This operator is unbounded if the network is robust and compact otherwise.

- We couple the neighbourhood of a uniformly chosen vertex with the genealogy of a killed branching random walk. This coupling is successful with high probability if up to log *N* vertices are explored.
- A sprinkling argument is used to establish the existence of a giant component from the local information. This means that we consider the approximating trees for a network with a slightly reduced edge density. If they survive percolation with positive probability, the remaining edges will connect the surviving trees with high probability, and hence a giant component exists.
- The underlying branching random walk has infinite offspring and a uncountable but compact typespace. Martingale arguments are used to show that the killed branching random walk survives percolation if 1/p is strictly smaller than the largest eigenvalue of an associated score operator. This operator is unbounded if the network is robust and compact otherwise.
- In the linear case the typespace degenerates to have just two elements. In this case eigenvalue calculations can be carried out explicitly.
