APTS: Statistical Modelling

March 2011 – slide 3

Basic Ideas

Why model?

George E. P. Box (1919–):

All models are wrong, but some models are useful.

- Some reasons we construct models:
 - to simplify reality (efficient representation);
 - to gain understanding;
 - to compare scientific, economic, ... theories;
 - to predict future events/data;
 - to control a process.
- We (statisticians!) rarely believe in our models, but regard them as temporary constructs subject to improvement.
- Often we have several and must decide which is preferable, if any.

APTS: Statistical Modelling

March 2011 – slide 5

Criteria for model selection

- Substantive knowledge, from prior studies, theoretical arguments, dimensional or other general considerations (often qualitative)
- Sensitivity to failure of assumptions (prefer models that are robustly valid)
- Quality of fit—residuals, graphical assessment (informal), or goodness-of-fit tests (formal)
- Prior knowledge in Bayesian sense (quantitative)
- Generalisability of conclusions and/or predictions: same/similar models give good fit for many different datasets
- ... but often we have just one dataset ...

APTS: Statistical Modelling

March 2011 – slide 6

Motivation

Even after applying these criteria (but also before!) we may compare many models:

- linear regression with p covariates, there are 2^p possible combinations of covariates (each in/out), before allowing for transformations, etc.— if $p = 20$ then we have a problem;
- choice of bandwidth $h > 0$ in smoothing problems
- the number of different clusterings of n individuals is a Bell number (starting from $n = 1$): 1, 2, 5, 15, 52, 203, 877, 4140, 21147, 115975, ...
- we may want to assess which among 5×10^5 SNPs on the genome may influence reaction to a new drug;
- ...

For reasons of economy we seek 'simple' models.

APTS: Statistical Modelling

March 2011 – slide 7

Albert Einstein (1879–1955)

'Everything should be made as simple as possible, **but no simpler.**'

APTS: Statistical Modelling

March 2011 – slide 8

William of Occam (?1288–?1348)

Occam's razor: **Entia non sunt multiplicanda sine necessitate: entities should not be multiplied beyond necessity.**

APTS: Statistical Modelling

March 2011 – slide 9

Setting

- To focus and simplify discussion we will consider parametric models, but the ideas generalise to semi-parametric and non-parametric settings
- We shall take generalised linear models (GLMs) as example of moderately complex parametric models:
 - Normal linear model has three key aspects:
 - ▷ *structure for covariates: linear predictor* $\eta = x^T\beta$;
 - ▷ *response distribution: $y \sim N(\mu, \sigma^2)$* ; and
 - ▷ *relation $\eta = \mu$ between $\mu = E(y)$ and η .*
 - GLM extends last two to
 - ▷ *y has density*

$$f(y; \theta, \phi) = \exp \left\{ \frac{y\theta - b(\theta)}{\phi} + c(y; \phi) \right\},$$

where θ depends on η ; *dispersion parameter* ϕ is often known; and

- ▷ $\eta = g(\mu)$, where g is monotone *link function*.

APTS: Statistical Modelling

March 2011 – slide 10

Logistic regression

- Commonest choice of link function for binary responses:

$$\Pr(Y = 1) = \pi = \frac{\exp(x^T \beta)}{1 + \exp(x^T \beta)}, \quad \Pr(Y = 0) = \frac{1}{1 + \exp(x^T \beta)},$$

giving linear model for log odds of 'success',

$$\log \left\{ \frac{\Pr(Y = 1)}{\Pr(Y = 0)} \right\} = \log \left(\frac{\pi}{1 - \pi} \right) = x^T \beta.$$

- Log likelihood for β based on independent responses y_1, \dots, y_n with covariate vectors x_1, \dots, x_n is

$$\ell(\beta) = \sum_{j=1}^n y_j x_j^T \beta - \sum_{j=1}^n \log \{1 + \exp(x_j^T \beta)\}$$

- Good fit gives small deviance $D = 2 \left\{ \ell(\tilde{\beta}) - \ell(\hat{\beta}) \right\}$, where $\hat{\beta}$ is model fit MLE and $\tilde{\beta}$ is unrestricted MLE.

APTS: Statistical Modelling

March 2011 – slide 11

Nodal involvement data

Table 1: Data on nodal involvement: 53 patients with prostate cancer have nodal involvement (r), with five binary covariates age etc.

			+	+	50	25.25	+	+	+	+	+	47	18.07

APTS: Statistical Modelling

March 2011 – slide 13

Nodal involvement

Adding terms

- always increases the log likelihood $\hat{\ell}$ and so reduces D ,
 - increases the number of parameters,
- so taking the model with highest $\hat{\ell}$ (lowest D) would give the full model

We need to trade off quality of fit (measured by D) and model complexity (number of parameters)

APTS: Statistical Modelling

March 2011 – slide 14

Log likelihood

- Given (unknown) **true model** $g(y)$, and **candidate model** $f(y; \theta)$, Jensen's inequality implies that

$$\int \log g(y)g(y) dy \geq \int \log f(y; \theta)g(y) dy, \quad (1)$$

with equality if and only if $f(y; \theta) \equiv g(y)$.

- If θ_g is the value of θ that maximizes the expected log likelihood on the right of (1), then it is natural to choose the candidate model that maximises

$$\bar{\ell}(\hat{\theta}) = n^{-1} \sum_{j=1}^n \log f(y_j; \hat{\theta}),$$

which should be an estimate of $\int \log f(y; \theta)g(y) dy$. However as $\bar{\ell}(\hat{\theta}) \geq \bar{\ell}(\theta_g)$, by definition of $\hat{\theta}$, this estimate is biased upwards.

- We need to correct for the bias, but in order to do so, need to understand the properties of likelihood estimators when the assumed model f is not the true model g .

APTS: Statistical Modelling

March 2011 – slide 15

Wrong model

Suppose the true model is g , that is, $Y_1, \dots, Y_n \stackrel{\text{iid}}{\sim} g$, but we assume that $Y_1, \dots, Y_n \stackrel{\text{iid}}{\sim} f(y; \theta)$. The log likelihood $\ell(\theta)$ will be maximised at $\hat{\theta}$, and

$$\bar{\ell}(\hat{\theta}) = n^{-1} \ell(\hat{\theta}) \xrightarrow{\text{a.s.}} \int \log f(y; \theta_g)g(y) dy, \quad n \rightarrow \infty,$$

where θ_g minimizes the Kullback–Leibler discrepancy

$$KL(f_\theta, g) = \int \log \left\{ \frac{g(y)}{f(y; \theta)} \right\} g(y) dy.$$

θ_g gives the density $f(y; \theta_g)$ closest to g in this sense, and $\hat{\theta}$ is determined by the finite-sample version of $\partial KL(f_\theta, g)/\partial \theta$, i.e.

$$0 = n^{-1} \sum_{j=1}^n \frac{\partial \log f(y_j; \hat{\theta})}{\partial \theta}.$$

APTS: Statistical Modelling

March 2011 – slide 16

Wrong model II

Theorem 1 Suppose the true model is g , that is, $Y_1, \dots, Y_n \stackrel{\text{iid}}{\sim} g$, but we assume that $Y_1, \dots, Y_n \stackrel{\text{iid}}{\sim} f(y; \theta)$. Then under mild regularity conditions the maximum likelihood estimator $\hat{\theta}$ satisfies

$$\hat{\theta} \sim N_p \{ \theta_g, I(\theta_g)^{-1} K(\theta_g) I(\theta_g)^{-1} \}, \quad (2)$$

where f_{θ_g} is the density minimising the Kullback–Leibler discrepancy between f_θ and g , I is the Fisher information for f , and K is the variance of the score statistic. The likelihood ratio statistic

$$W(\theta_g) = 2 \left\{ \ell(\hat{\theta}) - \ell(\theta_g) \right\} \sim \sum_{r=1}^p \lambda_r V_r,$$

where $V_1, \dots, V_p \stackrel{\text{iid}}{\sim} \chi_1^2$, and the λ_r are eigenvalues of $K(\theta_g)^{1/2} I_g(\theta_g)^{-1} K(\theta_g)^{1/2}$. Thus $E\{W(\theta_g)\} = \text{tr}\{I(\theta_g)^{-1} K(\theta_g)\}$.

Under the correct model, θ_g is the 'true' value of θ , $K(\theta) = I(\theta)$, $\lambda_1 = \dots = \lambda_p = 1$, and we recover the usual results.

APTS: Statistical Modelling

March 2011 – slide 17

Out-of-sample prediction

- We need to fix two problems with using $\bar{\ell}(\hat{\theta})$ to choose the best candidate model:
 - upward bias, as $\bar{\ell}(\hat{\theta}) \geq \bar{\ell}(\theta_g)$ because $\hat{\theta}$ is based on Y_1, \dots, Y_n ;
 - no penalisation if the dimension of θ increases.
- If we had another independent sample $Y_1^+, \dots, Y_n^+ \stackrel{\text{iid}}{\sim} g$ and computed

$$\bar{\ell}^+(\hat{\theta}) = n^{-1} \sum_{j=1}^n \log f(Y_j^+; \hat{\theta}),$$

then both problems disappear, suggesting that we choose the candidate model that maximises

$$E_g \left[E_g^+ \left\{ \bar{\ell}^+(\hat{\theta}) \right\} \right],$$

where the inner expectation is over the distribution of the Y_j^+ , and the outer expectation is over the distribution of $\hat{\theta}$.

APTS: Statistical Modelling

March 2011 – slide 18

Information criteria

- Previous results on wrong model give

$$E_g \left[E_g^+ \left\{ \bar{\ell}^+(\hat{\theta}) \right\} \right] \doteq \int \log f(y; \theta_g) g(y) dy - \frac{1}{2n} \text{tr} \{ I_g(\theta_g)^{-1} K(\theta_g) \},$$

where the second term is a penalty that depends on the model dimension.

- We want to estimate this based on Y_1, \dots, Y_n only, and get

$$E_g \left\{ \bar{\ell}(\hat{\theta}) \right\} \doteq \int \log f(y; \theta_g) g(y) dy + \frac{1}{2n} \text{tr} \{ I_g(\theta_g)^{-1} K(\theta_g) \},$$

- To remove the bias, we aim to maximise

$$\bar{\ell}(\hat{\theta}) - \frac{1}{n} \text{tr}(\hat{J}^{-1} \hat{K}),$$

where

$$\hat{K} = \sum_{j=1}^n \frac{\partial \log f(y_j; \hat{\theta})}{\partial \theta} \frac{\partial \log f(y_j; \hat{\theta})}{\partial \theta^T}, \quad \hat{J} = - \sum_{j=1}^n \frac{\partial^2 \log f(y_j; \hat{\theta})}{\partial \theta \partial \theta^T};$$

the latter is just the observed information matrix.

APTS: Statistical Modelling

March 2011 – slide 19

Information criteria

- Let $p = \dim(\theta)$ be the number of parameters for a model, and $\hat{\ell}$ the corresponding maximised log likelihood.
- For historical reasons we choose models that **minimise** similar criteria
 - $2(p - \hat{\ell})$ (AIC—Akaike Information Criterion)
 - $2\{\text{tr}(\hat{J}^{-1} \hat{K}) - \hat{\ell}\}$ (NIC—Network Information Criterion)
 - $2(\frac{1}{2}p \log n - \hat{\ell})$ (BIC—Bayes Information Criterion)
 - AIC_c, AIC_u, DIC, EIC, FIC, GIC, SIC, TIC, ...
 - Mallows $C_p = RSS/s^2 + 2p - n$ commonly used in regression problems, where RSS is residual sum of squares for candidate model, and s^2 is an estimate of the error variance σ^2 .

APTS: Statistical Modelling

March 2011 – slide 20

Nodal involvement data

AIC and BIC for 2^5 models for binary logistic regression model fitted to the nodal involvement data. Both criteria pick out the same model, with the three covariates *st*, *xr*, and *ac*, which has deviance $D = 19.64$. Note the sharper increase of BIC after the minimum.

APTS: Statistical Modelling

March 2011 – slide 21

Theoretical aspects

- We may suppose that the true underlying model is of infinite dimension, and that by choosing among our candidate models we hope to get as close as possible to this ideal model, using the data available.
- If so, we need some measure of distance between a candidate and the true model, and we aim to minimise this distance.
- A model selection procedure that selects the candidate closest to the truth for large n is called **asymptotically efficient**.
- An alternative is to suppose that the true model is among the candidate models.
- If so, then a model selection procedure that selects the true model with probability tending to one as $n \rightarrow \infty$ is called **consistent**.

APTS: Statistical Modelling

March 2011 – slide 22

Properties of AIC, NIC, BIC

- We seek to find the correct model by minimising $IC = c(n, p) - 2\hat{\ell}$, where the penalty $c(n, p)$ depends on sample size n and model dimension p
- Crucial aspect is behaviour of differences of IC.
- We obtain IC for the true model, and IC_+ for a model with one more parameter. Then

$$\begin{aligned} \Pr(IC_+ < IC) &= \Pr\left\{c(n, p+1) - 2\hat{\ell}_+ < c(n, p) - 2\hat{\ell}\right\} \\ &= \Pr\left\{2(\hat{\ell}_+ - \hat{\ell}) > c(n, p+1) - c(n, p)\right\}. \end{aligned}$$

and in large samples

$$\text{for AIC, } c(n, p+1) - c(n, p) = 2$$

$$\text{for NIC, } c(n, p+1) - c(n, p) \sim 2$$

$$\text{for BIC, } c(n, p+1) - c(n, p) = \log n$$

- In a regular case $2(\hat{\ell}_+ - \hat{\ell}) \sim \chi_1^2$, so as $n \rightarrow \infty$,

$$\Pr(IC_+ < IC) \rightarrow \begin{cases} 0.16, & \text{AIC, NIC,} \\ 0, & \text{BIC.} \end{cases}$$

Thus AIC and NIC have non-zero probability of over-fitting, even in very large samples, but BIC does not.

Linear Model

slide 24

Variable selection

- Consider normal linear model

$$Y_{n \times 1} = X_{n \times p}^\dagger \beta_{p \times 1} + \varepsilon_{n \times 1}, \quad \varepsilon \sim \mathcal{N}_n(0, \sigma^2 I_n),$$

where **design matrix** X^\dagger has full rank $p < n$ and columns x_r , for $r \in \mathcal{X} = \{1, \dots, p\}$. Subsets \mathcal{S} of \mathcal{X} correspond to subsets of columns.

- Terminology
 - the **true** model corresponds to subset $\mathcal{T} = \{r : \beta_r \neq 0\}$, and $|\mathcal{T}| = q < p$;
 - a **correct** model contains \mathcal{T} but has other columns also, corresponding subset \mathcal{S} satisfies $\mathcal{T} \subset \mathcal{S} \subset \mathcal{X}$ and $\mathcal{T} \neq \mathcal{S}$;
 - a **wrong** model has subset \mathcal{S} lacking some x_r for which $\beta_r \neq 0$, and so $\mathcal{T} \not\subset \mathcal{S}$.
- Aim to identify \mathcal{T} .
- If we choose a wrong model, have bias; if we choose a correct model, increase variance—seek to balance these.

Stepwise methods

- **Forward selection:** starting from model with constant only,
 1. add each remaining term separately to the current model;
 2. if none of these terms is significant, stop; otherwise
 3. update the current model to include the most significant new term; go to 1
- **Backward elimination:** starting from model with all terms,
 1. if all terms are significant, stop; otherwise
 2. update current model by dropping the term with the smallest F statistic; go to 1
- **Stepwise:** starting from an arbitrary model,
 1. consider 3 options—add a term, delete a term, swap a term in the model for one not in the model;
 2. if model unchanged, stop; otherwise go to 1

Backward selection chooses a model with seven covariates also chosen by minimising AIC.

APTS: Statistical Modelling

March 2011 – slide 28

Stepwise Methods: Comments

- Systematic search minimising AIC or similar over all possible models is preferable—not always feasible.
- Stepwise methods can fit models to purely random data—main problem is no objective function.
- Sometimes used by replacing F significance points by (arbitrary!) numbers, e.g. $F = 4$
- Can be improved by comparing AIC for different models at each step—uses AIC as objective function, but no systematic search.

APTS: Statistical Modelling

March 2011 – slide 29

Prediction error

- To identify \mathcal{T} , we fit candidate model

$$Y = X\beta + \varepsilon,$$

where columns of X are a subset \mathcal{S} of those of X^\dagger .

- Fitted value is

$$X\hat{\beta} = X\{(X^T X)^{-1} X^T Y\} = HY = H(\mu + \varepsilon) = H\mu + H\varepsilon,$$

where $H = X(X^T X)^{-1} X^T$ is the **hat matrix** and $H\mu = \mu$ if the model is correct.

- Following reasoning for AIC, suppose we also have independent dataset Y_+ from the true model, so $Y_+ = \mu + \varepsilon_+$
- Apart from constants, previous measure of prediction error is

$$\Delta(X) = n^{-1} \mathbb{E} \mathbb{E}_+ \left\{ (Y_+ - X\hat{\beta})^T (Y_+ - X\hat{\beta}) \right\},$$

with expectations over both Y_+ and Y .

APTS: Statistical Modelling

March 2011 – slide 30

Prediction error II

- Can show that

$$\Delta(X) = \begin{cases} n^{-1} \mu^T (I - H) \mu + (1 + p/n) \sigma^2, & \text{wrong model,} \\ (1 + q/n) \sigma^2, & \text{true model,} \\ (1 + p/n) \sigma^2, & \text{correct model;} \end{cases} \quad (6)$$

recall that $q < p$.

- **Bias:** $n^{-1} \mu^T (I - H) \mu > 0$ unless model is correct, and is reduced by including useful terms
- **Variance:** $(1 + p/n) \sigma^2$ increased by including useless terms
- Ideal would be to choose covariates X to minimise $\Delta(X)$: impossible—depends on unknowns μ, σ .
- Must estimate $\Delta(X)$

APTS: Statistical Modelling

March 2011 – slide 31

Example

$\Delta(X)$ as a function of the number of included variables p for data with $n = 20$, $q = 6$, $\sigma^2 = 1$. The minimum is at $p = q = 6$:

- there is a sharp decrease in bias as useful covariates are added;
- there is a slow increase with variance as the number of variables p increases.

APTS: Statistical Modelling

March 2011 – slide 32

Cross-validation

- If n is large, can split data into two parts (X', y') and (X^*, y^*) , say, and use one part to estimate model, and the other to compute prediction error; then choose the model that minimises

$$\hat{\Delta} = n'^{-1}(y' - X'\hat{\beta}^*)^T(y' - X'\hat{\beta}^*) = n'^{-1} \sum_{j=1}^{n'} (y'_j - x'_j \hat{\beta}^*)^2.$$

- Usually dataset is too small for this; use **leave-one-out cross-validation** sum of squares

$$n\hat{\Delta}_{CV} = CV = \sum_{j=1}^n (y_j - x_j^T \hat{\beta}_{-j})^2,$$

where $\hat{\beta}_{-j}$ is estimate computed without (x_j, y_j) .

- Seems to require n fits of model, but in fact

$$CV = \sum_{j=1}^n \frac{(y_j - x_j^T \hat{\beta})^2}{(1 - h_{jj})^2},$$

where h_{11}, \dots, h_{nn} are diagonal elements of H , and so can be obtained from one fit.

APTS: Statistical Modelling

March 2011 – slide 33

Cross-validation II

- Simpler (more stable?) version uses **generalised cross-validation** sum of squares

$$\text{GCV} = \sum_{j=1}^n \frac{(y_j - x_j^T \hat{\beta})^2}{\{1 - \text{tr}(H)/n\}^2}.$$

- Can show that

$$E(\text{GCV}) = \mu^T(I - H)\mu/(1 - p/n)^2 + n\sigma^2/(1 - p/n) \approx n\Delta(X) \quad (7)$$

so try and minimise GCV or CV.

- Many variants of cross-validation exist. Typically find that model chosen based on CV is somewhat unstable, and that GCV or k -fold cross-validation works better. Standard strategy is to split data into 10 roughly equal parts, predict for each part based on the other nine-tenths of the data, and find model that minimises this estimate of prediction error.

APTS: Statistical Modelling

March 2011 – slide 34

Other selection criteria

- Corrected version of AIC for models with normal responses:

$$\text{AIC}_c \equiv n \log \hat{\sigma}^2 + n \frac{1 + p/n}{1 - (p + 2)/n},$$

where $\hat{\sigma}^2 = \text{RSS}/n$. Related (unbiased) AIC_u replaces $\hat{\sigma}^2$ by $S^2 = \text{RSS}/(n - p)$.

- Mallows suggested

$$C_p = \frac{SS_p}{s^2} + 2p - n,$$

where SS_p is RSS for fitted model and s^2 estimates σ^2 .

- Comments:

- AIC tends to choose models that are too complicated; AIC_c cures this somewhat
- BIC chooses true model with probability $\rightarrow 1$ as $n \rightarrow \infty$, if the true model is fitted.

APTS: Statistical Modelling

March 2011 – slide 35

Simulation experiment

Number of times models were selected using various model selection criteria in 50 repetitions using simulated normal data for each of 20 design matrices. The true model has $p = 3$.

n		Number of covariates						
		1	2	3	4	5	6	7
10	C_p		131	504	91	63	83	128
	BIC		72	373	97	83	109	266
	AIC		52	329	97	91	125	306
	AIC_c	15	398	565	18	4		
20	C_p		4	673	121	88	61	53
	BIC		6	781	104	52	30	27
	AIC		2	577	144	104	76	97
	AIC_c		8	859	94	30	8	1
40	C_p			712	107	73	66	42
	BIC			904	56	20	15	5
	AIC			673	114	90	69	54
	AIC_c			786	105	52	41	16

APTS: Statistical Modelling

March 2011 – slide 36

Simulation experiment

Twenty replicate traces of AIC, BIC, and AIC_c , for data simulated with $n = 20$, $p = 1, \dots, 16$, and $q = 6$.

APTS: Statistical Modelling

March 2011 – slide 37

Simulation experiment

Twenty replicate traces of AIC, BIC, and AIC_c, for data simulated with $n = 40$, $p = 1, \dots, 16$, and $q = 6$.

APTS: Statistical Modelling

March 2011 – slide 38

Simulation experiment

Twenty replicate traces of AIC, BIC, and AIC_c, for data simulated with $n = 80$, $p = 1, \dots, 16$, and $q = 6$.

As n increases, note how

- AIC and AIC_c still allow some over-fitting, but BIC does not, and
- AIC_c approaches AIC.

APTS: Statistical Modelling

March 2011 – slide 39

Motivation

- 'Traditional' analysis methods presuppose that $p < n$, so the number of observations exceeds the number of covariates: tall thin design matrices
- Many modern datasets have design matrices that are short and fat: $p \gg n$, so the number of covariates (far) exceeds the number of observations—e.g., survival data (n a few hundred) with genetic information on individuals (p many thousands)
- Need approaches to deal with this
- Only possibility is to drop most of the covariates from the analysis, so the model has many fewer active covariates
 - usually impracticable in fitting to have $p > n$
 - anyway impossible to interpret when p too large
- Seek **sparse** solutions, in which coefficients of most covariates are set to zero, and only covariates with large coefficients are retained. One way to do this is by thresholding: kill small coefficients, and keep the rest.

APTS: Statistical Modelling

March 2011 – slide 41

Desiderata

Would like variable selection procedures that satisfy:

- **sparsity**—small estimates are reduced to zero by a threshold procedure; and
- **near unbiasedness**—the estimators almost provide the true parameters, when these are large and $n \rightarrow \infty$;
- **continuity**—the estimator is continuous in the data, to avoid instability in prediction.

None of the previous approaches is sparse, and stepwise selection (for example) is known to be highly unstable. To overcome this, we consider a **regularised** (or penalised) log likelihood of the form

$$\frac{1}{2} \sum_{j=1}^n \ell_j(x_j^T \beta; y_j) - n \sum_{r=1}^p p_\lambda(|\beta_r|),$$

where $p_\lambda(|\beta|)$ is a penalty discussed below.

APTS: Statistical Modelling

March 2011 – slide 42

Example: Lasso

- The **lasso** (least absolute selection and shrinkage operator) chooses β to minimise

$$(y - X\beta)^T(y - X\beta) \text{ such that } \sum_{r=1}^p |\beta_r| \leq \lambda,$$

for some $\lambda > 0$; call resulting estimator $\tilde{\beta}_\lambda$.

- $\lambda \rightarrow 0$ implies $\tilde{\beta}_\lambda \rightarrow 0$, and $\lambda \rightarrow \infty$ implies $\tilde{\beta}_\lambda \rightarrow \hat{\beta} = (X^T X)^{-1} X^T y$.
- Simple case: orthogonal design matrix $X^T X = I_p$, gives

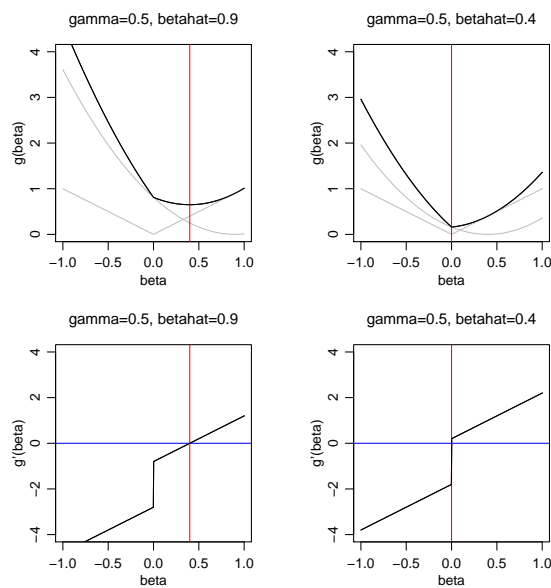

$$\tilde{\beta}_{\lambda,r} = \begin{cases} 0, & |\hat{\beta}_r| < \gamma, \\ \text{sign}(\hat{\beta}_r)(|\hat{\beta}_r| - \gamma), & \text{otherwise,} \end{cases} \quad r = 1, \dots, p. \quad (8)$$

- Call this **soft thresholding**.
- Computed using **least angle regression** algorithm (Efron et al., 2004, Annals of Statistics).

APTS: Statistical Modelling

March 2011 – slide 43

Soft thresholding

APTS: Statistical Modelling

March 2011 – slide 44

Graphical explanation

In each case aim to minimise the quadratic function subject to remaining inside the shaded region.

APTS: Statistical Modelling

March 2011 – slide 45

Lasso: Nuclear power data

Left: traces of coefficient estimates $\hat{\beta}_\lambda$ as constraint λ is relaxed, showing points at which the different covariates enter the model. Right: behaviour of Mallows' C_p as λ increases.

APTS: Statistical Modelling

March 2011 – slide 46

Penalties

Some (of many) possible penalty functions $p_\lambda(|\beta|)$, all with $\lambda > 0$:

- ridge regression** takes $\lambda|\beta|^2$;
- lasso** takes $\lambda|\beta|$;
- elastic net** takes $\lambda\{(1 - \alpha)|\beta| + \alpha|\beta|^2\}$, with $0 \leq \alpha < 1$;
- bridge regression** takes $\lambda|\beta|^q$, for $q > 0$;
- hard threshold** takes $\lambda^2 - (|\beta| - \lambda)^2 I(|\beta| < \lambda)$;
- smoothly clipped absolute deviation (SCAD)** takes

$$\begin{cases} \lambda|\beta|, & |\beta| < \lambda, \\ -(\beta^2 - 2a\lambda|\beta| + \lambda^2)/\{2(a - 1)\}, & \lambda < |\beta| < a\lambda, \\ (a + 1)\lambda^2/2, & |\beta| > a\lambda, \end{cases}$$

for some $a > 2$.

In least squares case with a single observation seek to minimise $\frac{1}{2}(z - \beta)^2 + p_\lambda(|\beta|)$, whose derivative

$$\text{sign}(\beta)\{|\beta| + \partial p_\lambda(|\beta|)/\partial\beta\} - z$$

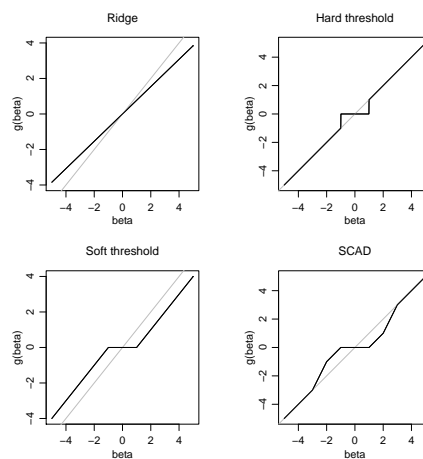

determines the properties of the estimator.

APTS: Statistical Modelling

March 2011 – slide 47

Some threshold functions

- Ridge—shrinkage but no selection; hard threshold—subset selection, unstable; soft threshold—lasso, biased; SCAD—continuous, selection, unbiased for large β , but non-monotone.

APTS: Statistical Modelling

March 2011 – slide 48

Properties of penalties

It turns out that to achieve

- sparsity**, the minimum of the function $|\beta| + \partial p_\lambda(|\beta|)/\partial\beta$ must be positive;
- near unbiasedness**, the penalty must satisfy $\partial p_\lambda(|\beta|)/\partial\beta \rightarrow 0$ when $|\beta|$ is large, so then the estimating function approaches $\beta - z$; and
- continuity**, the minimum of $|\beta| + \partial p_\lambda(|\beta|)/\partial\beta$ must be attained at $\beta = 0$.

The SCAD is constructed to have these properties, but there is no unique minimum to the resulting objective function, so numerically it is awkward.

APTS: Statistical Modelling

March 2011 – slide 49

Oracle

- Oracle:

A person or thing regarded as an infallible authority or guide.

- A **statistical oracle** says how to choose the model or bandwidth that will give us optimal estimation of the true parameter or function, but not the truth itself.
- In the context of variable selection, an oracle tells us which variables we should select, but not their coefficients.
- It turns out that under mild conditions on the model, and provided $\lambda \equiv \lambda_n \rightarrow 0$ and $\sqrt{n}\lambda_n \rightarrow \infty$ as $n \rightarrow \infty$, variable selection using the hard and SCAD penalties has an oracle property: the estimators of β work as well as *if* we had known in advance which covariates should be excluded.
- Same ideas extend to generalised linear models, survival analysis, and many other regression settings (Fan and Li, 2001, JASA).
- Harder: what happens when $p \rightarrow \infty$ also?

APTS: Statistical Modelling

March 2011 – slide 52

Bayesian inference

Parametric model for data y assumed to be realisation of $Y \sim f(y; \theta)$, where $\theta \in \Omega_\theta$.

Frequentist viewpoint (cartoon version):

- there is a true value of θ that generated the data;
- this 'true' value of θ is to be treated as an unknown constant;
- probability statements concern randomness in hypothetical replications of the data (possibly conditioned on an ancillary statistic).

Bayesian viewpoint (cartoon version):

- all ignorance may be expressed in terms of probability statements;
- a joint probability distribution for data and all unknowns can be constructed;
- Bayes' theorem should be used to convert prior beliefs $\pi(\theta)$ about unknown θ into posterior beliefs $\pi(\theta | y)$, conditioned on data;
- probability statements concern randomness of unknowns, conditioned on all known quantities.

APTS: Statistical Modelling

March 2011 – slide 53

Mechanics

- Separate from data, we have prior information about parameter θ summarised in density $\pi(\theta)$
- Data model $f(y | \theta) \equiv f(y; \theta)$
- Posterior density given by Bayes' theorem:

$$\pi(\theta | y) = \frac{\pi(\theta)f(y | \theta)}{\int \pi(\theta)f(y | \theta) d\theta}.$$

- $\pi(\theta | y)$ contains all information about θ , conditional on observed data y
- If $\theta = (\psi, \lambda)$, then inference for ψ is based on **marginal posterior density**

$$\pi(\psi | y) = \int \pi(\theta | y) d\lambda$$

APTS: Statistical Modelling

March 2011 – slide 54

Encompassing model

- Suppose we have M alternative models for the data, with respective parameters $\theta_1 \in \Omega_{\theta_1}, \dots, \theta_m \in \Omega_{\theta_m}$. Typically dimensions of Ω_{θ_m} are different.
- We enlarge the parameter space to give an **encompassing model** with parameter

$$\theta = (m, \theta_m) \in \Omega = \bigcup_{m=1}^M \{m\} \times \Omega_{\theta_m}.$$

- Thus need priors $\pi_m(\theta_m | m)$ for the parameters of each model, plus a prior $\pi(m)$ giving pre-data probabilities for each of the models; overall

$$\pi(m, \theta_m) = \pi(\theta_m | m)\pi(m) = \pi_m(\theta_m)\pi_m,$$

say.

- Inference about model choice is based on marginal posterior density

$$\pi(m | y) = \frac{\int f(y | \theta_m)\pi_m(\theta_m)\pi_m d\theta_m}{\sum_{m'=1}^M \int f(y | \theta_{m'})\pi_{m'}(\theta_{m'})\pi_{m'} d\theta_{m'}} = \frac{\pi_m f(y | m)}{\sum_{m'=1}^M \pi_{m'} f(y | m')}.$$

APTS: Statistical Modelling

March 2011 – slide 55

Inference

- Can write

$$\pi(m, \theta_m | y) = \pi(\theta_m | y, m)\pi(m | y),$$

so Bayesian updating corresponds to

$$\pi(\theta_m | m)\pi(m) \mapsto \pi(\theta_m | y, m)\pi(m | y)$$

and for each model $m = 1, \dots, M$ we need

- posterior probability $\pi(m | y)$, which involves the marginal likelihood $f(y | m) = \int f(y | \theta_m, m)\pi(\theta_m | m) d\theta_m$; and
- the posterior density $f(\theta_m | y, m)$.

- If there are just two models, can write

$$\frac{\pi(1 | y)}{\pi(2 | y)} = \frac{\pi_1 f(y | 1)}{\pi_2 f(y | 2)},$$

so the posterior odds on model 1 equal the prior odds on model 1 multiplied by the **Bayes factor** $B_{12} = f(y | 1)/f(y | 2)$.

APTS: Statistical Modelling

March 2011 – slide 56

Sensitivity of the marginal likelihood

Suppose the prior for each θ_m is $\mathcal{N}(0, \sigma^2 I_{d_m})$, where $d_m = \dim(\theta_m)$. Then, dropping the m subscript for clarity,

$$\begin{aligned} f(y | m) &= \sigma^{-d/2} (2\pi)^{-d/2} \int f(y | m, \theta) \prod_r \exp\{-\theta_r^2 / (2\sigma^2)\} d\theta_r \\ &\approx \sigma^{-d/2} (2\pi)^{-d/2} \int f(y | m, \theta) \prod_r d\theta_r, \end{aligned}$$

for a highly diffuse prior distribution (large σ^2). The Bayes factor for comparing the models is approximately

$$\frac{f(y | 1)}{f(y | 2)} \approx \sigma^{(d_2 - d_1)/2} g(y),$$

where $g(y)$ depends on the two likelihoods but is independent of σ^2 . Hence, *whatever the data tell us about the relative merits of the two models*, the Bayes factor in favour of the simpler model can be made arbitrarily large by increasing σ .

This illustrates **Lindley's paradox**, and implies that we must be careful when specifying prior dispersion parameters to compare models.

APTS: Statistical Modelling

March 2011 – slide 57

Model averaging

- If a quantity Z has the same interpretation for all models, it may be necessary to allow for model uncertainty:
 - in prediction, each model may be just a vehicle that provides a future value, not of interest *per se*;
 - physical parameters (means, variances, etc.) may be suitable for averaging, but care is needed.
- The predictive distribution for Z may be written

$$f(z | y) = \sum_{m=1}^M f(z | y, m) \Pr(m | y)$$

where

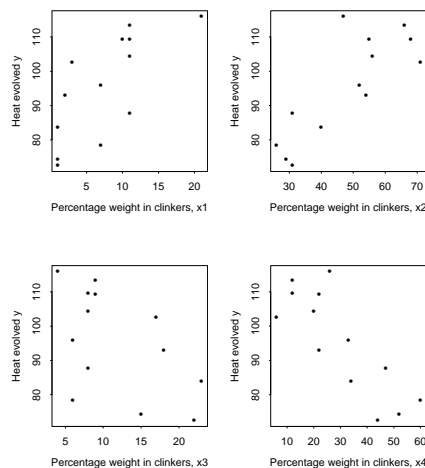

$$\Pr(m | y) = \frac{f(y | m) \Pr(m)}{\sum_{m'=1}^M f(y | m') \Pr(m')}$$

Posterior predictive densities for cement data. Predictive densities for a future observation y_+ with covariate values x_+ based on individual models are given as dotted curves. The heavy curve is the average density from all 16 models.

APTS: Statistical Modelling

March 2011 – slide 62

DIC

- How to compare complex models (e.g. hierarchical models, mixed models, Bayesian settings), in which the 'number of parameters' may:
 - outnumber the number of observations?
 - be unclear because of the regularisation provided by a prior density?
- Suppose model has 'Bayesian deviance'

$$D(\theta) = -2 \log f(y | \theta) + 2 \log f(y)$$

for some normalising function $f(y)$, and suppose that samples from the posterior density of θ are available and give $\bar{\theta} = E(\theta | y)$.

- One possibility is the **deviance information criterion (DIC)**

$$D(\bar{\theta}) + 2p_D,$$

where the number of associated parameters is

$$p_D = \overline{D(\theta)} - D(\bar{\theta}).$$

- This involves only (MCMC) samples from the posterior, no analytical computations, and reproduces AIC for some classes of models.

APTS: Statistical Modelling

March 2011 – slide 63

Minimum description length

Model selection can also be based on related ideas of **minimum description length (MDL)** or **minimum message length (MML)**, which use ideas from computer science—coding and information theory:

- idea is to choose encoding of data that minimises length of equivalent binary sequence, regarding all data as discrete;
- minimum message includes parameter estimates, data using optimal code based on parameter estimates, (and prior information);
- close links to AIC, BIC, etc.;
- see <http://www.mdl-research.org/> or tutorial on <http://homepages.cwi.nl/~pdg/ftp/mdlintro.pdf> to learn more.

APTS: Statistical Modelling

March 2011 – slide 64

Bayesian Variable Selection

slide 65

Variable selection

- In Bayesian context, must determine prior probability for the inclusion (or not) of each variable in the model.
- Common to use 'spike and slab' prior for coefficient θ :

$$\theta = \begin{cases} 0, & \text{with probability } 1 - p \\ \mathcal{N}(0, \tau^2), & \text{with probability } p, \end{cases}$$

corresponding to prior 'density'

$$\pi(\theta) = (1 - p)\delta(\theta) + p\tau^{-1}\phi(\theta/\tau), \quad \theta \in \mathbb{R},$$

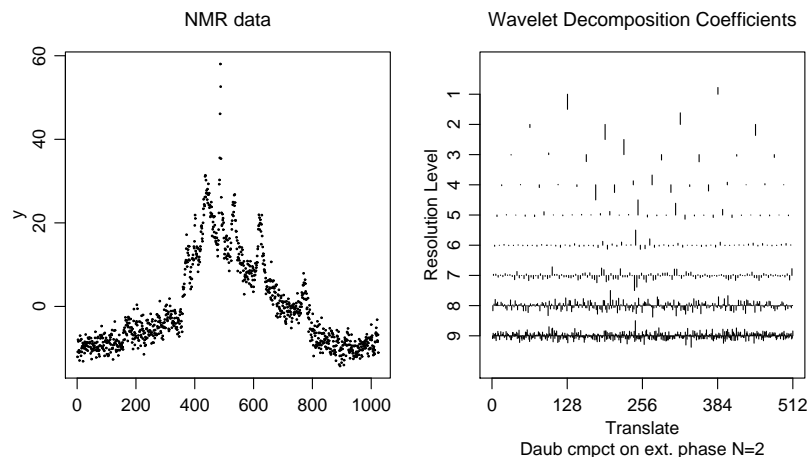

where $\delta(\theta)$ is the delta function putting unit mass at $\theta = 0$.

- Now find posterior for β based on data.
- Usually independent priors for each covariate, and typically need clever (dimension-jumping) MCMC.

APTS: Statistical Modelling

March 2011 – slide 66

Example: NMR data

Left: original data, with $n = 1024$

Right: orthogonal transformation into $n = 1024$ coefficients at different resolutions

APTS: Statistical Modelling

March 2011 – slide 67

Orthogonal transformation

- Model:** original data $X \sim \mathcal{N}_n(\mu, \sigma^2 I_n)$, where signal $\mu_{n \times 1}$ is perturbed by normal noise, giving noisy data $X_{n \times 1}$
- set $Y_{n \times 1} = W_{n \times n} X_{n \times 1}$, where $W^T W = W W^T = I_n$ is orthogonal
- choose W so that $\theta = W \mu$ should be 'sparse' (i.e. most elements of θ are zero)—good choice is wavelet coefficients (mathematical compression properties)
- 'kill' small coefficients of Y , which correspond to noise, giving $\tilde{\theta}_{n \times 1} = \text{kill}(Y) = \text{kill}(WX)$, say, then
- estimate signal μ by

$$\tilde{\mu} = W^T \tilde{\theta} = W^T (\text{kill}(WX)).$$

APTS: Statistical Modelling

March 2011 – slide 68

Posterior

If given θ , $Y \sim \mathcal{N}(\theta, \sigma^2)$, then the posterior 'density' is of form

$$\pi(\theta | y) = (1 - p_y) \delta(\theta) + p_y b^{-1} \phi\left(\frac{\theta - ay}{b}\right), \quad \theta \in \mathbb{R},$$

where

$$a = \tau^2 / (\tau^2 + \sigma^2), \quad b^2 = 1 / (1/\sigma^2 + 1/\tau^2),$$

and

$$p_y = \frac{p(\sigma^2 + \tau^2)^{-1/2} \phi\{y / (\sigma^2 + \tau^2)^{1/2}\}}{(1 - p)\sigma^{-1} \phi(y/\sigma) + p(\sigma^2 + \tau^2)^{-1/2} \phi\{y / (\sigma^2 + \tau^2)^{1/2}\}}$$

is the posterior probability that $\theta \neq 0$.

Summary statistic: **posterior median** $\tilde{\theta}$, for which $\Pr(\theta \leq \tilde{\theta} | y) = 0.5$. For small $|y|$, this gives $\tilde{\theta} = 0$. (Next slide)

APTS: Statistical Modelling

March 2011 – slide 69

Shrinkage

Prior CDF of θ (left), and posterior CDFs when $p = 0.5, \sigma = \tau = 1$, and $y = -2.5$ (centre), and $y = -1$ (right).

Red horizontal line: cumulative probability=0.5

Blue vertical line: data y

Green vertical line: posterior median $\tilde{\theta}$

APTS: Statistical Modelling

March 2011 – slide 70

Empirical Bayes

The parameters p, σ, τ are unknown. We estimate them by empirical Bayes:

- we note that the marginal density of y is

$$f(y) = (1-p)\sigma^{-1}\phi(y/\sigma) + p(\sigma^2 + \tau^2)^{-1/2}\phi\{y/(\sigma^2 + \tau^2)^{1/2}\}, \quad y \in \mathbb{R},$$

so if we have $y_1, \dots, y_n \stackrel{\text{iid}}{\sim} f$ we estimate p, σ, τ by maximising the log likelihood

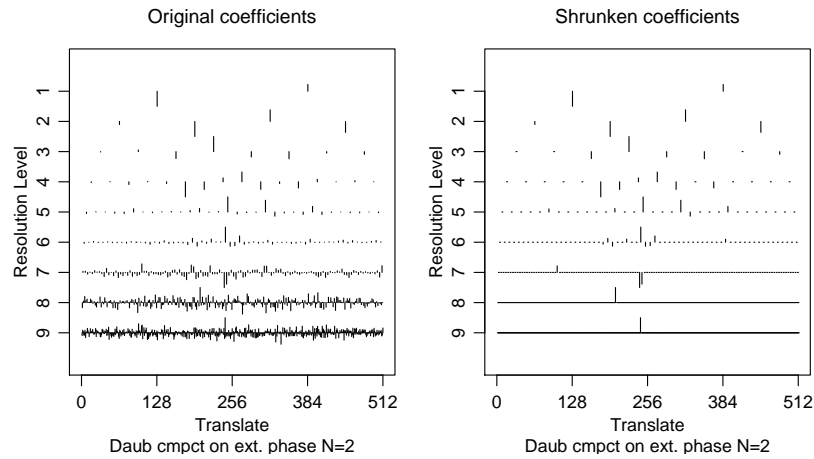

$$\ell(p, \sigma, \tau) = \sum_{j=1}^n \log f(y_j; p, \sigma, \tau).$$

- Here we obtain $\tilde{p} = 0.04$, $\tilde{\sigma} = 2.1$, and $\tilde{\tau} = 52.1$.
- Now compute the posterior medians $\tilde{\theta}_j$ corresponding to each y_j .

GLM recap

y_1, \dots, y_n are observations of response variables Y_1, \dots, Y_n assumed to be independently generated by a distribution of the same exponential family form, with means $\mu_i \equiv E(Y_i)$ linked to explanatory variables X_1, X_2, \dots, X_p through

$$g(\mu_i) = \eta_i \equiv \beta_0 + \sum_{r=1}^p \beta_r x_{ir} \equiv x_i^T \beta$$

GLMs have proved remarkably effective at modelling real world variation in a wide range of application areas.

March 2011 – slide 78

GLM failure

However, situations frequently arise where GLMs do not adequately describe observed data. This can be due to a number of reasons including:

- The mean model cannot be appropriately specified as there is dependence on an unobserved (or unobservable) explanatory variable.
- There is excess variability between experimental units beyond that implied by the mean/variance relationship of the chosen response distribution.
- The assumption of independence is not appropriate.
- Complex multivariate structure in the data requires a more flexible model class

APTS: Statistical Modelling

March 2011 – slide 79

Example 1: toxoplasmosis

The table below gives data on the relationship between rainfall (x) and the proportions of people with toxoplasmosis (y/m) for 34 cities in El Salvador.

City	y	x	City	y	x	City	y	x
1	5/18	1620	12	3/5	1800	23	3/10	1973
2	15/30	1650	13	8/10	1800	24	1/6	1976
3	0/1	1650	14	0/1	1830	25	1/5	2000
4	2/4	1735	15	53/75	1834	26	0/1	2000
5	2/2	1750	16	7/16	1871	27	7/24	2050
6	2/8	1750	17	24/51	1890	28	46/82	2063
7	2/12	1756	18	3/10	1900	29	7/19	2077
8	6/11	1770	19	23/43	1918	30	9/13	2100
9	33/54	1770	20	3/6	1920	31	4/22	2200
10	8/13	1780	21	0/1	1920	32	4/9	2240
11	41/77	1796	22	3/10	1936	33	8/11	2250
						34	23/37	2292

Example

Toxoplasmosis data and fitted models

Example

Fitting various binomial logistic regression models relating toxoplasmosis incidence to rainfall:

Model	df	deviance
Constant	33	74.21
Linear	32	74.09
Quadratic	31	74.09
Cubic	30	62.62

So evidence in favour of the cubic over other models, but a poor fit ($\chi^2 = 58.21$ on 30df).

This is an example of **overdispersion** where residual variability is greater than would be predicted by the specified mean/variance relationship

$$\text{var}(Y) = \frac{\mu(1 - \mu)}{m}.$$

APTS: Statistical Modelling

March 2011 – slide 83

Example

Toxoplasmosis residual plot

APTS: Statistical Modelling

March 2011 – slide 84

Quasi-likelihood

A quasi-likelihood approach to accounting for overdispersion models the mean and variance, but stops short of a full probability model for Y .

For a model specified by the mean relationship $g(\mu_i) = \eta_i = x_i^T \beta$, and variance $\text{var}(Y_i) = \sigma^2 V(\mu_i)/m_i$, the quasi-likelihood equations are

$$\sum_{i=1}^n x_i \frac{y_i - \mu_i}{\sigma^2 V(\mu_i) g'(\mu_i)/m_i} = 0$$

If $V(\mu_i)/m_i$ represents $\text{var}(Y_i)$ for a standard distribution from the exponential family, then these equations can be solved for β using standard GLM software.

Provided the mean and variance functions are correctly specified, asymptotic normality for $\hat{\beta}$ still holds. The dispersion parameter σ^2 can be estimated using

$$\hat{\sigma}^2 \equiv \frac{1}{n - p - 1} \sum_{i=1}^n \frac{m_i (y_i - \hat{\mu}_i)^2}{V(\hat{\mu}_i)}$$

APTS: Statistical Modelling

March 2011 – slide 85

Quasi-likelihood for toxoplasmosis data

Assuming the same mean model as before, but $\text{var}(Y_i) = \sigma^2 \mu_i (1 - \mu_i)/m_i$, we obtain $\hat{\sigma}^2 = 1.94$ with $\hat{\beta}$ (and corresponded fitted mean curves) as before.

Comparing cubic with constant model, one now obtains

$$F = \frac{(74.21 - 62.62)/3}{1.94} = 1.99$$

which provides much less compelling evidence in favour of an effect of rainfall on toxoplasmosis incidence.

APTS: Statistical Modelling

March 2011 – slide 86

Reasons

To construct a full probability model in the presence of overdispersion, it is necessary to consider **why** overdispersion might be present.

Possible reasons include:

- There may be an important explanatory variable, other than rainfall, which we haven't observed.
- Or there may be many other features of the cities, possibly unobservable, all having a small individual effect on incidence, but a larger effect in combination. Such effects may be individually undetectable – sometimes described as *natural excess variability between units*.

APTS: Statistical Modelling

March 2011 – slide 87

Reasons: unobserved heterogeneity

When part of the linear predictor is 'missing' from the model,

$$\eta_i^{\text{true}} = \eta_i^{\text{model}} + \eta_i^{\text{diff}}$$

We can compensate for this, in modelling, by assuming that the missing $\eta_i^{\text{diff}} \sim F$ in the population. Hence, given η_i^{model}

$$\mu_i \equiv g^{-1}(\eta_i^{\text{model}} + \eta_i^{\text{diff}}) \sim G$$

where G is the distribution induced by F . Then

$$E(Y_i) = E_G[E(Y_i | \mu_i)] = E_G(\mu_i)$$

$$\text{var}(Y_i) = E_G(V(\mu_i)/m_i) + \text{var}_G(\mu_i)$$

APTS: Statistical Modelling

March 2011 – slide 88

Direct models

One approach is to model the Y_i directly, by specifying an appropriate form for G .

For example, for the toxoplasmosis data, we might specify a **beta-binomial** model, where

$$\mu_i \sim \text{Beta}(k\mu_i^*, k[1 - \mu_i^*])$$

leading to

$$E(Y_i) = \mu_i^*, \quad \text{var}(Y_i) = \frac{\mu_i^*(1 - \mu_i^*)}{m_i} \left(1 + \frac{m_i - 1}{k + 1} \right)$$

with $(m_i - 1)/(k + 1)$ representing an overdispersion factor.

APTS: Statistical Modelling

March 2011 – slide 89

Direct models: fitting

Models which explicitly account for overdispersion can, in principle, be fitted using your preferred approach, e.g. the beta-binomial model has likelihood

$$f(y | \mu^*, k) \propto \prod_{i=1}^n \frac{\Gamma(k\mu_i^* + m_i y_i) \Gamma\{k(1 - \mu_i^*) + m_i(1 - y_i)\} \Gamma(k)}{\Gamma(k\mu_i^*) \Gamma\{k(1 - \mu_i^*)\} \Gamma(k + m_i)}.$$

Similarly the corresponding model for count data specifies a gamma distribution for the Poisson mean, leading to a *negative binomial* marginal distribution for Y_i .

However, these models have limited flexibility and can be difficult to fit, so an alternative approach is usually preferred.

APTS: Statistical Modelling

March 2011 – slide 90

A random effects model for overdispersion

A more flexible, and extensible approach models the excess variability by including an extra term in the linear predictor

$$\eta_i = x_i^T \beta + u_i \quad (9)$$

where the u_i can be thought of as representing the 'extra' variability between units, and are called **random effects**.

The model is completed by specifying a distribution F for u_i in the population – almost always, we use

$$u_i \sim N(0, \sigma^2)$$

for some unknown σ^2 .

We set $E(u_i) = 0$, as an unknown mean for u_i would be unidentifiable in the presence of the intercept parameter β_0 .

APTS: Statistical Modelling

March 2011 – slide 91

Random effects: likelihood

The parameters of this random effects model are usually considered to be (β, σ^2) and therefore the likelihood is given by

$$\begin{aligned} f(\mathbf{y} | \beta, \sigma^2) &= \int f(\mathbf{y} | \beta, \mathbf{u}, \sigma^2) f(\mathbf{u} | \beta, \sigma^2) d\mathbf{u} \\ &= \int f(\mathbf{y} | \beta, \mathbf{u}) f(\mathbf{u} | \sigma^2) d\mathbf{u} \\ &= \int \prod_{i=1}^n f(y_i | \beta, u_i) f(u_i | \sigma^2) du_i \end{aligned} \quad (10)$$

where $f(y_i | \beta, u_i)$ arises from our chosen exponential family, with linear predictor (9) and $f(u_i | \sigma^2)$ is a univariate normal p.d.f.

Often no further simplification of (10) is possible, so computation needs careful consideration – we will come back to this later.

APTS: Statistical Modelling

March 2011 – slide 92

Toxoplasmosis example revisited

We can think of the toxoplasmosis proportions Y_i in each city (i) as arising from the sum of binary variables, Y_{ij} , representing the toxoplasmosis status of individuals (j), so $m_i Y_i = \sum_{j=1}^{m_i} Y_{ij}$. Then

$$\begin{aligned} \text{var}(Y_i) &= \frac{1}{m_i^2} \sum_{j=1}^{m_i} \text{var}(Y_{ij}) + \frac{1}{m_i^2} \sum_{j \neq k} \text{cov}(Y_{ij}, Y_{ik}) \\ &= \frac{\mu_i(1 - \mu_i)}{m_i} + \frac{1}{m_i^2} \sum_{j \neq k} \text{cov}(Y_{ij}, Y_{ik}) \end{aligned}$$

So any positive correlation between individuals induces overdispersion in the counts.

Dependence: reasons

There may be a number of plausible reasons why the responses corresponding to units within a given **cluster** are dependent (in the toxoplasmosis example, cluster = city)

One compelling reason is the unobserved heterogeneity discussed previously.

In the 'correct' model (corresponding to η_i^{true}), the toxoplasmosis status of individuals, Y_{ij} , are independent, so

$$Y_{ij} \perp\!\!\!\perp Y_{ik} \mid \eta_i^{\text{true}} \Leftrightarrow Y_{ij} \perp\!\!\!\perp Y_{ik} \mid \eta_i^{\text{model}}, \eta_i^{\text{diff}}$$

However, in the absence of knowledge of η_i^{diff}

$$Y_{ij} \not\perp\!\!\!\perp Y_{ik} \mid \eta_i^{\text{model}}$$

Hence conditional (given η_i^{diff}) independence between units in a common cluster i becomes marginal dependence, when marginalised over the population distribution F of unobserved η_i^{diff} .

Random effects and dependence

The correspondence between positive intra-cluster correlation and unobserved heterogeneity suggests that intra-cluster dependence might be modelled using random effects, For example, for the individual-level toxoplasmosis data

$$Y_{ij} \overset{\text{ind}}{\sim} \text{Bernoulli}(\mu_{ij}), \quad \log \frac{\mu_{ij}}{1 - \mu_{ij}} = x_{ij}^T \beta + u_i, \quad u_i \sim N(0, \sigma^2)$$

which implies

$$Y_{ij} \not\perp\!\!\!\perp Y_{ik} \mid \beta, \sigma^2$$

Intra-cluster dependence arises in many applications, and random effects provide an effective way of modelling it.

Marginal models

Random effects modelling is not the only way of accounting for intra-cluster dependence.

A **marginal model** models $\mu_{ij} \equiv E(Y_{ij})$ as a function of explanatory variables, through $g(\mu_{ij}) = x_{ij}^T \beta$, and also specifies a variance relationship $\text{var}(Y_{ij}) = \sigma^2 V(\mu_{ij})/m_{ij}$ and a model for $\text{corr}(Y_{ij}, Y_{ik})$, as a function of μ and possibly additional parameters.

It is important to note that the parameters β in a marginal model have a different interpretation from those in a random effects model, because for the latter

$$E(Y_{ij}) = E(g^{-1}[x_{ij}^T \beta + u_i]) \neq g^{-1}(x_{ij}^T \beta) \quad (\text{unless } g \text{ is linear}).$$

- A random effects model describes the mean response at the subject level ('subject specific')
- A marginal model describes the mean response across the population ('population averaged')

APTS: Statistical Modelling

March 2011 – slide 97

GEEs

As with the quasi-likelihood approach above, marginal models do not generally provide a full probability model for Y . Nevertheless, β can be estimated using **generalised estimating equations (GEEs)**.

The GEE for estimating β in a marginal model is of the form

$$\sum_i \left(\frac{\partial \mu_i}{\partial \beta} \right)^T \text{var}(Y_i)^{-1} (Y_i - \mu_i) = 0$$

where $Y_i = (Y_{ij})$ and $\mu_i = (\mu_{ij})$

Consistent covariance estimates are available for GEE estimators.

Furthermore, the approach is generally robust to mis-specification of the correlation structure.

For the rest of this module, we focus on fully specified probability models.

APTS: Statistical Modelling

March 2011 – slide 98

Clustered data

Examples where data are collected in clusters include:

- Studies in biometry where **repeated measures** are made on experimental units. Such studies can effectively mitigate the effect of between-unit variability on important inferences.
- Agricultural field trials, or similar studies, for example in engineering, where experimental units are arranged within **blocks**
- Sample surveys where collecting data within clusters or **small areas** can save costs

Of course, other forms of dependence exist, for example spatial or serial dependence induced by arrangement in space or time of units of observation. This will be a focus of APTS: Spatial and Longitudinal Data Analysis.

APTS: Statistical Modelling

March 2011 – slide 99

Example 2: Rat growth

The table below is extracted from a data set giving the weekly weights of 30 young rats.

Rat	Week				
	1	2	3	4	5
1	151	199	246	283	320
2	145	199	249	293	354
3	147	214	263	312	328
4	155	200	237	272	297
5	135	188	230	280	323
6	159	210	252	298	331
7	141	189	231	275	305
8	159	201	248	297	338
...
30	153	200	244	286	324

APTS: Statistical Modelling

March 2011 – slide 100

Example

Rat growth data

APTS: Statistical Modelling

March 2011 – slide 101

A simple model

Letting Y represent weight, and X represent week, we can fit the simple linear regression

$$y_{ij} = \beta_0 + \beta_1 x_{ij} + \epsilon_{ij}$$

with resulting estimates $\hat{\beta}_0 = 156.1$ (2.25) and $\hat{\beta}_1 = 43.3$ (0.92)

Residuals show clear evidence of an unexplained difference between rats

APTS: Statistical Modelling

March 2011 – slide 102

Model elaboration

Naively adding a (fixed) effect for animal gives

$$y_{ij} = \beta_0 + \beta_1 x_{ij} + u_i + \epsilon_{ij}.$$

Residuals show evidence of a further unexplained difference between rats in terms of dependence on x .

More complex cluster dependence required.

APTS: Statistical Modelling

March 2011 – slide 103

Linear mixed models

A linear mixed model (LMM) for observations $y = (y_1, \dots, y_n)$ has the general form

$$Y \sim N(\mu, \Sigma), \quad \mu = X\beta + Zb, \quad b \sim N(0, \Sigma_b), \tag{11}$$

where X and Z are matrices containing values of explanatory variables. Usually, $\Sigma = \sigma^2 I_n$.

A typical example for clustered data might be

$$Y_{ij} \stackrel{\text{ind}}{\sim} N(\mu_{ij}, \sigma^2), \quad \mu_{ij} = x_{ij}^T \beta + z_{ij}^T b_i, \quad b_i \stackrel{\text{ind}}{\sim} N(0, \Sigma_b^*), \tag{12}$$

where x_{ij} contain the explanatory data for cluster i , observation j and (normally) z_{ij} contains that sub-vector of x_{ij} which is allowed to exhibit extra between cluster variation in its relationship with Y . In the simplest (random intercept) case, $z_{ij} = (1)$, as in equation (9).

LMM example

A plausible LMM for k clusters with n_1, \dots, n_k observations per cluster, and a single explanatory variable x (e.g. the rat growth data) is

$$y_{ij} = \beta_0 + b_{0i} + (\beta_1 + b_{1i})x_{ij} + \epsilon_{ij}, \quad (b_{0i}, b_{1i})^T \stackrel{\text{ind}}{\sim} N(0, \Sigma_b^*).$$

This fits into the general LMM framework (11) with $\Sigma = \sigma^2 I_n$ and

$$X = \begin{pmatrix} 1 & x_{11} \\ \vdots & \vdots \\ 1 & x_{kn_k} \end{pmatrix}, \quad Z = \begin{pmatrix} Z_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & Z_k \end{pmatrix}, \quad Z_i = \begin{pmatrix} 1 & x_{i1} \\ \vdots & \vdots \\ 1 & x_{in_i} \end{pmatrix},$$

$$\beta = \begin{pmatrix} \beta_0 \\ \beta_1 \end{pmatrix}, \quad b = \begin{pmatrix} b_1 \\ \vdots \\ b_k \end{pmatrix}, \quad b_i = \begin{pmatrix} b_{0i} \\ b_{1i} \end{pmatrix}, \quad \Sigma_b = \begin{pmatrix} \Sigma_b^* & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \Sigma_b^* \end{pmatrix}$$

where Σ_b^* is an unspecified 2×2 positive definite matrix.

Variance components

The term **mixed model** refers to the fact that the linear predictor $X\beta + Zb$ contains both fixed effects β and random effects b .

Under an LMM, we can write the marginal distribution of Y directly as

$$Y \sim N(X\beta, \Sigma + Z\Sigma_b Z^T) \quad (13)$$

where X and Z are matrices containing values of explanatory variables.

Hence $\text{var}(Y)$ is comprised of two **variance components**.

Other ways of describing LMMs for clustered data, such as (12) (and their generalised linear model counterparts) are as **hierarchical** models or **multilevel** models. This reflects the two-stage structure of the model, a conditional model for $Y_{ij} | b_i$, followed by a marginal model for the random effects b_i .

Sometimes the hierarchy can have further levels, corresponding to clusters nested within clusters, for example, patients within wards within hospitals, or pupils within classes within schools.

APTS: Statistical Modelling

March 2011 – slide 107

Discussion: Why random effects?

It would be perfectly possible to take a model such as (12) and ignore the final component, leading to fixed cluster effects (as we did for the rat growth data).

The main issue with such an approach is that inferences, particularly predictive inferences can then only be made about those clusters present in the observed data.

Random effects models, on the other hand, allow inferences to be extended to a wider population (at the expense of a further modelling assumption).

It also can be the case, as in (9) with only one observation per 'cluster', that fixed effects are not identifiable, whereas random effects can still be estimated. Similarly, some treatment variables must be applied at the cluster level, so fixed treatment and cluster effects are aliased.

Finally, random effects allow 'borrowing strength' across clusters by shrinking fixed effects towards a common mean.

APTS: Statistical Modelling

March 2011 – slide 108

Discussion: A Bayesian perspective

A Bayesian LMM supplements (11) with prior distributions for β , Σ and Σ_b .

In one sense the distinction between fixed and random effects is much less significant, as in the full Bayesian probability specification, both β and b , as unknowns have probability distributions, $f(\beta)$ and $f(b) = \int f(b | \Sigma_b) f(\Sigma_b) d\Sigma_b$

Indeed, prior distributions for 'fixed' effects are sometimes constructed in a hierarchical fashion, for convenience (for example, heavy-tailed priors are often constructed this way).

The main difference is the possibility that random effects for which we have no relevant data (for example cluster effects for unobserved clusters) might need to be predicted.

APTS: Statistical Modelling

March 2011 – slide 109

LMM fitting

The likelihood for $(\beta, \Sigma, \Sigma_b)$ is available directly from (13) as

$$f(y | \beta, \Sigma, \Sigma_b) \propto |V|^{-1/2} \exp\left(\frac{1}{2}(y - X\beta)^T V^{-1}(y - X\beta)\right) \quad (14)$$

where $V = \Sigma + Z\Sigma_b Z^T$. This likelihood can be maximised directly (usually numerically).

However, mles for variance parameters of LMMs can have large downward bias (particularly in cluster models with a small number of observed clusters).

Hence estimation by **REML** – *REstricted* (or *REsidual*) Maximum Likelihood is usually preferred.

REML proceeds by estimating the variance parameters (Σ, Σ_b) using a *marginal likelihood* based on the residuals from a (generalised) least squares fit of the model $E(Y) = X\beta$.

APTS: Statistical Modelling

March 2011 – slide 110

REML

In effect, REML maximizes the likelihood of any linearly independent sub-vector of $(I_n - H)y$ where $H = X(X^T X)^{-1} X^T$ is the usual hat matrix. As

$$(I_n - H)y \sim N(0, (I_n - H)V(I_n - H))$$

this likelihood will be free of β . It can be written in terms of the full likelihood (14) as

$$f(r | \Sigma, \Sigma_b) \propto f(y | \hat{\beta}, \Sigma, \Sigma_b) |X^T V X|^{1/2} \quad (15)$$

where

$$\hat{\beta} = (X^T V^{-1} X)^{-1} X^T V^{-1} y \quad (16)$$

is the usual generalised least squares estimator given known V .

Having first obtained $(\hat{\Sigma}, \hat{\Sigma}_b)$ by maximising (15), $\hat{\beta}$ is obtained by plugging the resulting \hat{V} into (16).

Note that REML maximised likelihoods cannot be used to compare different fixed effects specifications, due to the dependence of 'data' r in $f(r | \Sigma, \Sigma_b)$ on X .

APTS: Statistical Modelling

March 2011 – slide 111

Estimating random effects

A natural predictor \tilde{b} of the random effect vector b is obtained by minimising the mean squared prediction error $E[(\tilde{b} - b)^T(\tilde{b} - b)]$ where the expectation is over both b and y .

This is achieved by

$$\tilde{b} = E(b | y) = (Z^T \Sigma^{-1} Z + \Sigma_b^{-1})^{-1} Z^T \Sigma^{-1} (y - X\beta) \quad (17)$$

giving the **Best Linear Unbiased Predictor** (BLUP) for b , with corresponding variance

$$\text{var}(b | y) = (Z^T \Sigma^{-1} Z + \Sigma_b^{-1})^{-1}$$

The estimates are obtained by plugging in $(\hat{\beta}, \hat{\Sigma}, \hat{\Sigma}_b)$, and are **shrunk** towards 0, in comparison with equivalent fixed effects estimators.

Any component, b_k of b with no relevant data (for example a cluster effect for an as yet unobserved cluster) corresponds to a null column of Z , and then $\tilde{b}_k = 0$ and $\text{var}(b_k | y) = [\Sigma_b]_{kk}$, which may be estimated if, as is usual, b_k shares a variance with other random effects.

APTS: Statistical Modelling

March 2011 – slide 112

Bayesian estimation: the Gibbs sampler

Bayesian estimation in LMMs (and their generalised linear model counterparts) generally proceeds using **Markov Chain Monte Carlo (MCMC)** methods, in particular approaches based on the **Gibbs sampler**. Such methods have proved very effective.

MCMC computation provides posterior summaries, by **generating a dependent** sample from the posterior distribution of interest. Then, any posterior expectation can be estimated by the corresponding Monte Carlo sample mean, densities can be estimated from samples etc.

MCMC will be covered in detail in APTS: Computer Intensive Statistics. Here we simply describe the (most basic) Gibbs sampler.

To generate from $f(y_1, \dots, y_n)$, (where the component y_i s are allowed to be multivariate) the Gibbs sampler starts from an arbitrary value of y and updates components (sequentially or otherwise) by generating from the conditional distributions $f(y_i | y_{\setminus i})$ where $y_{\setminus i}$ are all the variables other than y_i , set at their currently generated values.

Hence, to apply the Gibbs sampler, we require conditional distributions which are available for sampling.

APTS: Statistical Modelling

March 2011 – slide 113

Bayesian estimation for LMMs

For the LMM

$$Y \sim N(\mu, \Sigma), \quad \mu = X\beta + Zb, \quad b \sim N(0, \Sigma_b)$$

with corresponding prior densities $f(\beta)$, $f(\Sigma)$, $f(\Sigma_b)$, we obtain the *conditional* posterior distributions

$$\begin{aligned} f(\beta \mid y, \text{rest}) &\propto \phi(y - Zb; X\beta, \Sigma) f(\beta) \\ f(b \mid y, \text{rest}) &\propto \phi(y - X\beta; Zb, \Sigma) \phi(b; 0, \Sigma_b) \\ f(\Sigma \mid y, \text{rest}) &\propto \phi(y - X\beta - Zb; 0, \Sigma) f(\Sigma) \\ f(\Sigma_b \mid y, \text{rest}) &\propto \phi(b; 0, \Sigma_b) f(\Sigma_b) \end{aligned}$$

where $\phi(y; \mu, \Sigma)$ is a $N(\mu, \Sigma)$ p.d.f. evaluated at y .

We can exploit **conditional conjugacy** in the choices of $f(\beta)$, $f(\Sigma)$, $f(\Sigma_b)$ making the conditionals above of known form and hence straightforward to sample from. The conditional independence $(\beta, \Sigma) \perp\!\!\!\perp \Sigma_b \mid b$ is also helpful.

See Practical 3 for further details.

APTS: Statistical Modelling

March 2011 – slide 114

Example: Rat growth revisited

Here, we consider the model

$$y_{ij} = \beta_0 + b_{0i} + (\beta_1 + b_{1i})x_{ij} + \epsilon_{ij}, \quad (b_{0i}, b_{1i})^T \stackrel{\text{iid}}{\sim} N(0, \Sigma_b)$$

where $\epsilon_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, \sigma^2)$ and Σ_b is an unspecified covariance matrix. This model allows for random (cluster specific) slope and intercept.

Estimates obtained by REML (ML in brackets) are

Parameter	Estimate	Standard error
β_0	156.05	2.16 (2.13)
β_1	43.27	0.73 (0.72)
$\Sigma_{00}^{1/2} = s.d.(b_0)$	10.93 (10.71)	
$\Sigma_{11}^{1/2} = s.d.(b_1)$	3.53 (3.46)	
$Corr(b_0, b_1)$	0.18 (0.19)	

As expected ML variances are smaller, but not by much.

APTS: Statistical Modelling

March 2011 – slide 115

Example: Fixed v. random effect estimates

The shrinkage of random effect estimates towards a common mean is clearly illustrated.

Random effects estimates ‘borrow strength’ across clusters, due to the Σ_b^{-1} term in (17). Extent of this is determined by cluster similarity. This is usually considered to be a desirable behaviour.

APTS: Statistical Modelling

March 2011 – slide 116

Random effect shrinkage

The following simple example illustrates (from a Bayesian perspective) why and how random effects are shrunk to a common value.

Suppose that y_1, \dots, y_n satisfy

$$y_j | \theta_j \stackrel{\text{iid}}{\sim} N(\theta_j, v_j), \quad \theta_1, \dots, \theta_n | \mu \stackrel{\text{iid}}{\sim} N(\mu, \sigma^2), \quad \mu \sim N(\mu_0, \tau^2),$$

where $v_1, \dots, v_n, \sigma^2, \mu_0$ and τ^2 are assumed known here. Then, the usual posterior calculations give us

$$E(\mu | y) = \frac{\mu_0/\tau^2 + \sum y_j/(\sigma^2 + v_j)}{1/\tau^2 + \sum 1/(\sigma^2 + v_j)}, \quad \text{var}(\mu | y) = \frac{1}{1/\tau^2 + \sum 1/(\sigma^2 + v_j)},$$

and

$$E(\theta_j | y) = (1 - w)E(\mu | y) + wy_j,$$

where

$$w = \frac{\sigma^2}{\sigma^2 + v_j}.$$

APTS: Statistical Modelling

March 2011 – slide 117

Example: Diagnostics

Normal Q-Q plots of intercept (panel 1) and slope (panel 2) random effects and residuals v. week (panel 3)

Evidence of a common quadratic effect, confirmed by AIC (1036 v. 1099) and BIC (1054 v. 1114) based on full ML fits. AIC would also include a cluster quadratic effect (BIC equivocal).

APTS: Statistical Modelling

March 2011 – slide 118

Generalised linear mixed models

Generalised linear mixed models (GLMMs) generalise LMMs to non-normal data, in the obvious way:

$$Y_i \stackrel{\text{ind}}{\sim} F(\cdot | \mu_i, \sigma^2), \quad g(\mu) \equiv \begin{pmatrix} g(\mu_1) \\ \vdots \\ g(\mu_n) \end{pmatrix} = X\beta + Zb, \quad b \sim N(0, \Sigma_b) \quad (18)$$

where $F(\cdot | \mu_i, \sigma^2)$ is an exponential family distribution with $E(Y) = \mu$ and $\text{var}(Y) = \sigma^2 V(\mu)/m$ for known m . Commonly (e.g. Binomial, Poisson) $\sigma^2 = 1$, and we shall assume this from here on.

It is not necessary that the distribution for the random effects b is normal, but this usually fits. It is possible (but beyond the scope of this module) to relax this.

APTS: Statistical Modelling

March 2011 – slide 119

GLMM example

A plausible GLMM for binary data in k clusters with n_1, \dots, n_k observations per cluster, and a single explanatory variable x (e.g. the toxoplasmosis data at individual level) is

$$Y_{ij} \stackrel{\text{ind}}{\sim} \text{Bernoulli}(\mu_i), \quad \log \frac{\mu_i}{1 - \mu_i} = \beta_0 + b_{0i} + \beta_1 x_{ij}, \quad b_{0i} \stackrel{\text{ind}}{\sim} N(0, \sigma_b^2) \quad (19)$$

[note: no random slope here]. This fits into the general GLMM framework (18) with

$$X = \begin{pmatrix} 1 & x_{11} \\ \vdots & \vdots \\ 1 & x_{kn_k} \end{pmatrix}, \quad Z = \begin{pmatrix} Z_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & Z_k \end{pmatrix}, \quad Z_i = \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix},$$

$$\beta = (\beta_0, \beta_1)^T, \quad b = (b_{01}, \dots, b_{0k})^T, \quad \Sigma_b = \sigma_b^2 I_k$$

[or equivalent binomial representation for city data, with clusters of size 1.]

APTS: Statistical Modelling

March 2011 – slide 120

GLMM likelihood

The marginal distribution for the observed Y in a GLMM does not usually have a convenient closed-form representation.

$$\begin{aligned} f(y | \beta, \Sigma_b) &= \int f(y | \beta, b, \Sigma_b) f(b | \beta, \Sigma_b) db \\ &= \int f(y | \beta, b) f(b | \Sigma_b) db \\ &= \int \prod_{i=1}^n f(y_i | g^{-1}([X\beta + Zb]_i)) f(b | \Sigma_b) db. \end{aligned} \quad (20)$$

For **nested** random effects structures, some simplification is possible. For example, for (19)

$$f(y | \beta, \sigma_b^2) \propto \prod_{i=1}^n \int \frac{\exp(\sum_j y_{ij}(\beta_0 + b_{0i} + \beta_1 x_{ij}))}{\{1 + \exp(\sum_j y_{ij}(\beta_0 + b_{0i} + \beta_1 x_{ij}))\}^{n_k}} \phi(b_{0i}; 0, \sigma_b^2) db_{0i}$$

a product of one-dimensional integrals.

APTS: Statistical Modelling

March 2011 – slide 121

GLMM fitting: quadrature

Fitting a GLMM by likelihood methods requires some method for approximating the integrals involved.

The most reliable when the integrals are of low dimension is to use Gaussian quadrature (see APTS: Statistical computing). For example, for a one-dimensional cluster-level random intercept b_i we might use

$$\begin{aligned} \int \prod_j f(y_{ij} | g^{-1}(x_i^T \beta + b_i)) \phi(b_i | 0, \sigma_b^2) db_i \\ \approx \sum_{q=1}^Q w_q \prod_j f(y_{ij} | g^{-1}(x_i^T \beta + b_{iq})) \end{aligned}$$

for suitably chosen weights ($w_q, q = 1, \dots, Q$) and quadrature points ($b_{iq}, q = 1, \dots, Q$)

Effective quadrature approaches use information about the mode and dispersion of the integrand (can be done adaptively).

For multi-dimensional b_i , quadrature rules can be applied recursively, but performance (in fixed time) diminishes rapidly with dimension.

APTS: Statistical Modelling

March 2011 – slide 122

GLMM fitting: Penalised quasi-likelihood

An alternative approach to fitting a GLMM uses penalised quasi-likelihood (PQL).

The most straightforward way of thinking about PQL is to consider the adjusted dependent variable v constructed when computing mles for a GLM using Fisher scoring

$$v_i = (y_i - \mu_i)g'(\mu_i) + \eta_i$$

Now, for a GLMM,

$$E(v | b) = \eta = X\beta + Zb$$

and

$$\text{var}(v | b) = W^{-1} = \text{diag}(\text{var}(y_i)g'(\mu_i)^2),$$

where W is the weight matrix used in Fisher scoring.

APTS: Statistical Modelling

March 2011 – slide 123

GLMM fitting: PQL continued

Hence, approximating the conditional distribution of v by a normal distribution, we have

$$v \sim N(X\beta + Zb, W^{-1}), \quad b \sim N(0, \Sigma_b) \quad (21)$$

where v and W also depend on β and b .

PQL proceeds by iteratively estimating β , b and Σ_b for the linear mixed model (21) for v , updating v and W at each stage, based on the current estimates of β and b .

An alternative justification for PQL is as using a Laplace-type approximation to the integral in the GLMM likelihood.

A full Laplace approximation (expanding the complete log-integrand, and evaluating the Hessian matrix at the mode) is an alternative, equivalent to one-point Gaussian quadrature.

APTS: Statistical Modelling

March 2011 – slide 124

GLMM fitting: discussion

Using PQL, estimates of random effects b come 'for free'. With Gaussian quadrature, some extra effort is required to compute $E(b | y)$ – further quadrature is an obvious possibility.

There are drawbacks with PQL, and the best advice is to use it with caution.

- It can fail badly when the normal approximation that justifies it is invalid (for example for binary observations)
- As it does not use a full likelihood, model comparison should not be performed using PQL maximised 'likelihoods'

Likelihood inference for GLMMs remains an area of active research and vigorous debate. Recent approaches include HGLMs (hierarchical GLMs) where inference is based on the h-likelihood $f(y | \beta, b)f(b | \Sigma)$.

APTS: Statistical Modelling

March 2011 – slide 125

Bayesian estimation for GLMMs

Bayesian estimation in GLMMs, as in LMMs, is generally based on the Gibbs sampler. For the GLMM

$$Y_i \stackrel{\text{ind}}{\sim} F(\cdot | \mu), \quad g(\mu) = X\beta + Zb, \quad b \sim N(0, \Sigma_b)$$

with corresponding prior densities $f(\beta)$ and $f(\Sigma_b)$, we obtain the *conditional* posterior distributions

$$f(\beta | y, \text{rest}) \propto f(\beta) \prod_i f(y_i | g^{-1}(X\beta + Zb))$$

$$f(b | y, \text{rest}) \propto \phi(b; 0, \Sigma_b) \prod_i f(y_i | g^{-1}(X\beta + Zb))$$

$$f(\Sigma_b | y, \text{rest}) \propto \phi(b; 0, \Sigma_b) f(\Sigma_b)$$

For a conditionally conjugate choice of $f(\Sigma_b)$, $f(\Sigma_b | y, \text{rest})$ is straightforward to sample from. The conditionals for β and b are not generally available for direct sampling, but there are a number of ways of modifying the basic approach to account for this.

APTS: Statistical Modelling

March 2011 – slide 126

Toxoplasmosis revisited

Estimates and standard errors obtained by ML (quadrature), Laplace and PQL for the individual-level model

$$Y_{ij} \stackrel{\text{ind}}{\sim} \text{Bernoulli}(\mu_i), \quad \log \frac{\mu_i}{1 - \mu_i} = \beta_0 + b_{0i} + \beta_1 x_{ij}, \quad b_{0i} \stackrel{\text{ind}}{\sim} N(0, \sigma_b^2)$$

Parameter	Estimate (s.e.)		
	ML	Laplace	PQL
β_0	-0.1343 (1.440)	-0.1384 (1.488)	-0.150 (1.392)
$\beta_1 (\times 10^6)$	5.930 (745.7)	7.215 (770.2)	-5.711 (721.7)
σ_b	0.5132	0.5209	0.4911
AIC	65.75	65.96	'65.98'

APTS: Statistical Modelling

March 2011 – slide 127

Toxoplasmosis continued

Estimates and standard errors obtained by ML (quadrature), Laplace and PQL for the extended model

$$\log \frac{\mu_i}{1 - \mu_i} = \beta_0 + b_{0i} + \beta_1 x_{ij} + \beta_2 x_{ij}^2 + \beta_3 x_{ij}^3.$$

Parameter	Estimate (s.e.)		
	ML	Laplace	PQL
β_0	-335.5 (136.6)	-335.0 (136.3)	-330.8 (140.7)
β_1	0.5238 (0.2118)	0.5231 (0.2112)	0.5166 (0.2180)
$\beta_2 (\times 10^4)$	-2.710 (1.089)	-2.706 (1.086)	-2.674 (1.121)
$\beta_3 (\times 10^8)$	4.463 (1.857)	4.636 (1.852)	4.583 (1.910)
σ_b	0.4232	0.4171	0.4508
AIC	63.84	63.97	'64.03'

So for this example, a good agreement between the different computational methods. Some evidence for the cubic model over the linear model.

APTS: Statistical Modelling

March 2011 – slide 128

Conditional independence and graphical representations

slide 129

The role of conditional independence

In modelling clustered data, the requirement is often (as in the toxoplasmosis example above) to construct a model to incorporate both non-normality and dependence. There are rather few 'off-the-shelf' models for dependent observations (and those that do exist, such as the multivariate normal, often require strong assumptions which may be hard to justify in practice).

The 'trick' with GLMMs was to model dependence via a series of **conditionally independent** sub-models for the observations y given the random effects b , with dependence induced by marginalising over the distribution of b .

De Finetti's theorem provides some theoretical justification for modelling dependent random variables as conditionally independent given some unknown parameter (which we here denote by ϕ).

APTS: Statistical Modelling

March 2011 – slide 130

De Finetti's theorem

De Finetti's theorem states (approximately) that any y_1, \dots, y_n which can be thought of as a finite subset of an **exchangeable** infinite sequence of random variables y_1, y_2, \dots , has a joint density which can be written as

$$f(y) = \int f(\phi) \prod_{i=1}^n f(y_i | \phi) d\phi$$

for some $f(\phi)$, $f(y_i | \phi)$. Hence the y_i can be modelled as conditionally independent given ϕ .

An *exchangeable* infinite sequence is one for which any finite subsequence has a distribution which is invariant under permutation of the labels of its components.

We can invoke this as an argument for treating as conditionally independent any set of variables about which our prior belief is symmetric.

APTS: Statistical Modelling

March 2011 – slide 131

Complex stochastic models

In many applications we want to model a multivariate response and/or to incorporate a complex (crossed or hierarchically nested) cluster structure amongst the observations.

The same general approach, splitting the model up into small components, with a potentially rich conditional independence structure linking them facilitates both model construction and understanding, and (potentially) computation.

APTS: Statistical Modelling

March 2011 – slide 132

Conditional independence graphs

An extremely useful tool, for model description, model interpretation, and to assist identifying efficient methods for computation is the **directed acyclic graph (DAG)** representing the model.

Denote by $Y = (Y_1, \dots, Y_\ell)$ the collection of elements of the model which are considered random (given a probability distribution). Then the model is a (parametric) description of the joint distribution $f(y)$, which we can decompose as

$$f(y) = f(y_1) f(y_2 | y_1) \cdots f(y_\ell | y_1, \dots, y_{\ell-1}) = \prod_i f(y_i | y_{<i})$$

where $y_{<i} = \{y_1, \dots, y_{i-1}\}$. Now, for certain orderings of the variables in Y , the model may admit conditional independences, exhibited through $f(y_i | y_1, \dots, y_{i-1})$ being functionally free of y_j for one or more $j < i$. This is expressed as

$$Y_i \perp\!\!\!\perp Y_j | Y_{<i \setminus j}$$

where $Y_{<i \setminus j} = \{Y_1, \dots, Y_{j-1}, Y_{j+1}, \dots, Y_{i-1}\}$.

APTS: Statistical Modelling

March 2011 – slide 133

DAGs

The directed acyclic graph (DAG) representing the probability model, decomposed as

$$f(y) = \prod_i f(y_i | y_{<i})$$

consists of a vertex (or node) for each Y_i , together with an directed edge (arrow) **to** each Y_j **from** each $Y_i, i < j$ such that $f(y_j | y_{<j})$ depends on y_i . For example, the model

$$f(y_1, y_2, y_3) = f(y_1)f(y_2 | y_1)f(y_3 | y_2)$$

is represented by the DAG

The conditional independence of Y_1 and Y_3 given Y_2 is represented by the absence of a directed edge from Y_1 to Y_3 .

APTS: Statistical Modelling

March 2011 – slide 134

DAG for a GLMM

The DAG for the general GLMM

$$Y_i \stackrel{\text{ind}}{\sim} F(\cdot | \mu_i, \sigma^2), \quad g(\mu) = X\beta + Zb, \quad b \sim N(0, \Sigma_b)$$

consists, in its most basic form of two nodes:

It can be informative to include parameters and explanatory data in the DAG. Such fixed (non-stochastic) quantities are often denoted by a different style of vertex.

It may also be helpful to consider the components of Y as separate vertices.

APTS: Statistical Modelling

March 2011 – slide 135

DAG for a Bayesian GLMM

A Bayesian model is a full joint probability model, across both the variables treated as stochastic in a classical approach, and any unspecified model parameters. The marginal probability distribution for the parameters represents the prior (to observing data) uncertainty about these quantities.

The appropriate DAG for a Bayesian GLMM reflects this, augmenting the DAG on the previous slide to:

where ϕ_σ , ϕ_Σ and ϕ_β are *hyperparameters* – fixed inputs into the prior distributions for σ^2 , σ_b and β respectively.

APTS: Statistical Modelling

March 2011 – slide 136

DAG properties

Suppose we have a DAG representing our model for a collection of random variables $Y = (Y_1, \dots, Y_\ell)$ where the ordering of the Y_i s is chosen such that all edges in the DAG are from lower to higher numbered vertices. [This must be possible for an acyclic graph, but there will generally be more than one possible ordering]. Then the joint distribution for Y factorises as

$$f(y) = \prod_i f(y_i | pa[y_i])$$

where $pa[y_i]$ represents the subset of $\{y_j, j < i\}$ with edges **to** y_i . Such variables are called the **parents** of y_i .

APTS: Statistical Modelling

March 2011 – slide 137

The local Markov property

A natural consequence of the DAG factorisation of the joint distribution of Y is the **local Markov property for DAGS**. *This states that any variable Y_i is conditionally independent of its non-descendants, given its parents.*

A descendent of Y_i is any variable in $\{Y_j, j > i\}$ which can be reached in the graph by following a sequence of edges **from** Y_i (respecting the direction of the edges).

For example, for the simple DAG above

the conditional independence of Y_3 and Y_1 given Y_2 is an immediate consequence of the local Markov property.

APTS: Statistical Modelling

March 2011 – slide 138

The local Markov property – limitations

Not all useful conditional independence properties of DAG models follow immediately from the local Markov property. For example, for the Bayesian GLMM

the posterior distribution is conditional on observed Y , for which the local Markov property is unhelpful, as Y is not a parent of any other variable.

To learn more about conditional independences arising from a DAG, it is necessary to construct the corresponding **undirected conditional independence graph**.

APTS: Statistical Modelling

March 2011 – slide 139

Undirected graphs

An undirected conditional independence graph for Y consists of a vertex for each Y_i , together with a set of undirected edges (lines) between vertices such that **absence** of an edge between two vertices Y_i and Y_j implies the conditional independence

$$Y_i \perp\!\!\!\perp Y_j \mid Y_{\setminus\{i,j\}}$$

where $Y_{\setminus\{i,j\}}$ is the set of variables excluding Y_i and Y_j .

From a DAG, we can obtain the corresponding undirected conditional independence graph via a two stage process

- First we *moralise* the graph by adding an (undirected) edge between ('marrying') any two vertices which have a *child* in common, and which are not already joined by an edge.
- Then we replace all directed edges by undirected edges.

APTS: Statistical Modelling

March 2011 – slide 140

Undirected graphs: examples

APTS: Statistical Modelling

March 2011 – slide 141

Global Markov property

For an undirected conditional independence graph, the **global Markov property** states that any two variables, Y_i and Y_j say, are conditionally independent given any subset Y_{sep} of the other variables which *separate* Y_i and Y_j in the graph.

We say that Y_{sep} separates Y_i and Y_j in an undirected graph if any path from Y_i to Y_j via edges in the graph must pass through a variable in Y_{sep} .

APTS: Statistical Modelling

March 2011 – slide 142

Undirected graph for Bayesian GLMM

The DAG for the Bayesian GLMM

has corresponding undirected graph (for the stochastic vertices)

The conditional independence of (β, σ^2) and Σ_b given b (and Y) is immediately obvious.

APTS: Statistical Modelling

March 2011 – slide 143

Markov equivalence

Any moral DAG (one which has no 'unmarried' parents) is **Markov equivalent** to its corresponding undirected graph (i.e. it encodes exactly the same conditional independence structure).

Conversely, the vertices of any **decomposable** undirected graph (one with no chordless cycles of four or more vertices) can be numbered so that replacing the undirected edges by directed edges from lower to higher numbered vertices produces a Markov equivalent DAG.

Such a numbering is called a **perfect** numbering for the graph, and is not unique.

It immediately follows that the Markov equivalence classes for DAGs can have (many) more than one member, each of which implies the same model for the data (in terms of conditional independence structure)

The class of DAGs is clearly much larger than the class of undirected graphs, and encompasses a richer range of conditional independence structures.

APTS: Statistical Modelling

March 2011 – slide 149

Introduction

Missing data arises in many practical applications. Typically, our data might appear (with missing observations indicated by *) as

Unit (i)	Variable (j)				
	1	2	3	...	p
1	y_{11}	y_{12}	y_{13}	...	y_{1p}
2	y_{21}	*	y_{23}	...	y_{2p}
3	*	y_{32}	*	...	*
4	*	y_{42}	y_{43}	...	y_{4p}
...
n	y_{n1}	*	y_{n3}	...	y_{np}

Variables which have missing observations in our data frame are said to be subject to **item nonresponse**. When there are units with no available data whatsoever, that is referred to as **unit nonresponse**.

If the variables can be ordered so that, for any unit i , (y_{ij} is missing) \Rightarrow (y_{ik} is missing for all $k > j$), the missing data pattern is said to be **monotone** (e.g. longitudinal dropout, special cases like Example 2).

APTS: Statistical Modelling

March 2011 – slide 150

Issues

Missing data creates two major problems for analysis.

- Suppose that we have a model $f(y | \theta)$, for which the likelihood is tractable. When certain y_{ij} are missing, the likelihood for inference must be based on the observed data distribution

$$f(y_{\text{obs}} | \theta) = \int f(y_{\text{obs}}, y_{\text{mis}} | \theta) dy_{\text{mis}} \quad (22)$$

where the subscripts obs and mis refer to observed and missing components, respectively. It is typically much more difficult to compute (22) than $f(y | \theta)$ for fully observed data.

- Even when it can be computed, the likelihood (22) is only valid for inference about θ under the assumption that the fact that certain observations are missing provides no information about θ .

APTS: Statistical Modelling

March 2011 – slide 151

Models

To formalise this, it is helpful to introduce a series of binary response indicator variables r_1, \dots, r_p , where

$$r_{ij} = 1 \Leftrightarrow y_{ij} \text{ is observed, } i = 1, \dots, n; j = 1, \dots, p.$$

We factorise the joint distribution of (y, r) into a data model for y and a (conditional) response model for r

$$f(y, r | \theta, \phi) = f(y | \theta)f(r | y, \phi).$$

Then the likelihood for the observed data, (y_{obs}, r) is

$$f(y_{\text{obs}}, r | \theta, \phi) = \int f(y_{\text{obs}}, y_{\text{mis}} | \theta)f(r | y_{\text{obs}}, y_{\text{mis}}, \phi)dy_{\text{mis}}. \quad (23)$$

In this set-up inference for θ should be based on (23), but there are situations when it is valid to **ignore** the missing data mechanism (and the corresponding variable r) and base inference for θ on the simpler $f(y_{\text{obs}} | \theta)$.

APTS: Statistical Modelling

March 2011 – slide 152

Ignorability

If $R \perp\!\!\!\perp Y_{\text{mis}} | Y_{\text{obs}}, \phi$ then $f(r | y_{\text{obs}}, y_{\text{mis}}, \phi)$ in (23) can be replaced by $f(r | y_{\text{obs}}, \phi)$, and (23) is simplified to:

$$f(y_{\text{obs}}, r | \theta, \phi) = f(y_{\text{obs}} | \theta)f(r | y_{\text{obs}}, \phi). \quad (24)$$

Hence, the likelihood for (θ, ϕ) factorises and *provided that θ and ϕ are independent* (in a functional sense for likelihood analysis, and in the usual stochastic sense for Bayesian analysis) inference for θ can be based on $f(y_{\text{obs}} | \theta)$.

- Any missing data model which satisfies the two requirements above, namely $[R \perp\!\!\!\perp Y_{\text{mis}} | Y_{\text{obs}}, \phi]$ and $[\phi \text{ independent of } \theta]$ is said to be **ignorable**. Otherwise, it is nonignorable.
- Missing data which satisfies $R \perp\!\!\!\perp Y_{\text{mis}} | Y_{\text{obs}}, \phi$ is said to be **missing at random (MAR)**
- Missing data which satisfies the stronger condition $R \perp\!\!\!\perp Y_{\text{mis}}, Y_{\text{obs}} | \phi$ is said to be **missing completely at random (MCAR)**. For MCAR data, correct (but potentially highly sub-optimal) inferences can be obtained by *complete case analysis*.

APTS: Statistical Modelling

March 2011 – slide 153

Inference under ignorability

For monotone missing data patterns, it may be possible to deal with $f(y_{\text{obs}} | \theta)$ directly. For example, suppose that the $Y_i = (Y_{i1}, \dots, Y_{ip})$ are conditionally independent given θ , and furthermore that

$$f(y_i | \theta) = \prod_j f(y_{ij} | y_{i,<j}, \theta_j)$$

where $\theta = (\theta_1, \dots, \theta_p)$ is a partition into distinct components. Then

$$f(y_{\text{obs}} | \theta) = \prod_i f(y_{i,\text{obs}} | \theta) = \prod_i \prod_{j=1}^{k_i} f(y_{ij} | y_{i,<j}, \theta_j)$$

where k_i is the 'last' observed variable for unit i . Hence the likelihood for θ factorises into individual components.

Otherwise, methods for inference in the presence of an ignorable missing data mechanism typically exploit the fact the full data analysis, based on $f(y | \theta)$ is tractable (assuming that it is!)

APTS: Statistical Modelling

March 2011 – slide 154

Gibbs sampler

For Bayesian analysis, this typically involves generating a sequence of values $\{\theta^t, y_{\text{mis}}^t, t = 1, \dots\}$ from the joint posterior distribution $f(\theta, y_{\text{mis}} | y_{\text{obs}})$ using a Gibbs sampler iteratively sampling

- the model-based conditional for $Y_{\text{mis}} | \theta, y_{\text{obs}}$.
- the complete data posterior conditional for $\theta | Y_{\text{mis}}, y_{\text{obs}}$

Often, both of these are convenient for sampling.

The subsample $\{\theta^t, t = 1, \dots\}$ may then be considered as being drawn from the marginal posterior for $\theta | y_{\text{obs}}$, as required.

This is sometimes referred to as **data augmentation**.

APTS: Statistical Modelling

March 2011 – slide 155

EM algorithm

For maximum likelihood, it is often the case that a corresponding iterative algorithm can be constructed by taking the Gibbs sampler steps above and replacing generation from conditionals with (i) taking expectation (for Y_{mis}) and (ii) likelihood maximisation (for θ), respectively.

- for the current θ^t construct the expected log-likelihood $E[\log f(Y_{\text{mis}}, y_{\text{obs}} | \theta) | y_{\text{obs}}, \theta^t]$
- maximise this expected log-likelihood w.r.t. θ to obtain θ^{t+1}

This is the EM algorithm, of which more details will be presented shortly. The maximisation (M) step is generally straightforward, and for many models, so is the expectation (E) step.

APTS: Statistical Modelling

March 2011 – slide 156

Nonignorable models

If considered appropriate, then a nonignorable missing data mechanism can be incorporated in $f(y, r | \theta, \phi)$. A **selection model** utilises the decomposition

$$f(y, r | \theta, \phi) = f(y | \theta)f(r | y, \phi).$$

where a nonignorable model incorporates dependence of R on Y_{mis} .

Alternatively, a **pattern mixture model** decomposes $f(y, r | \theta, \phi)$ as

$$f(y, r | \theta, \phi) = f(y | r, \theta)f(r | \phi).$$

Pattern mixture models tend to be less intuitively appealing, but may be easier to analyse (particularly for monotone missing data patterns).

Under either specification, inference must be based on the observed data likelihood

$$f(y_{\text{obs}}, r | \theta, \phi) = \int f(y_{\text{obs}}, y_{\text{mis}}, r | \theta, \phi) dy_{\text{mis}}.$$

Gibbs sampling or EM can be used for computation, but convergence may be slow.

APTS: Statistical Modelling

March 2011 – slide 157

A simple selection model

Consider the selection model

$$Y \sim N(\theta_1, \theta_2), \quad \Pr(R = 1 | Y = y) = \frac{\exp(\phi_0 + \phi_1 y)}{1 + \exp(\phi_0 + \phi_1 y)}$$

An example of $f(y | r = 1)$, the marginal density for y_{obs} is

for $(\theta_1, \theta_2, \phi_0, \phi_1) = (0, 1, 0, 2)$.

The **selection effect** is quite subtle and will clearly be hard to estimate accurately.

APTS: Statistical Modelling

March 2011 – slide 158

Nonignorable model issues

In the previous example, it will be impossible to distinguish, on the basis of observed data only, between the proposed selection model, and an ignorable model where the population distribution of y is naturally slightly skewed.

Generally, nonignorable model inferences are sensitive to model assumptions, and there exist alternative models which cannot be effectively compared on the basis of fit to observed data alone.

Furthermore, inferences from alternative, equally well-fitting models may be very different, as the following (artificial) example illustrates.

y_1	y_2 (Observed)		y_2 (Missing)		
	A	B	A	B	
1	6	18			16
2	3	9			8
3	3	27			10

APTS: Statistical Modelling

March 2011 – slide 159

Sensitivity example

Missing data estimates based on the ignorable model $R_2 \perp\!\!\!\perp Y_2 \mid Y_1$

y_1	y_2 (Observed)		y_2 (Missing)		
	A	B	A	B	
1	6	18	4	12	
2	3	9	2	6	
3	3	27	1	9	

Missing data estimates based on the nonignorable model $R_2 \perp\!\!\!\perp Y_1 \mid Y_2$

y_1	y_2 (Observed)		y_2 (Missing)		
	A	B	A	B	
1	6	18	14	2	
2	3	9	7	1	
3	3	27	7	3	

Potentially very different inferences for the marginal distribution of y_2 .

Pragmatic approaches are based on investigating sensitivity to a range of missing data assumptions.

APTS: Statistical Modelling

March 2011 – slide 160

Basic idea

- Many statistical models simplify when written in terms of unobserved **latent variable** U in addition to the observed data Y . The latent variable
 - may really exist, for example, when $Y = I(U > c)$ for some continuous U ('do you earn less than £ c per year?');
 - may be imaginary—something called IQ is said to underlie scores on intelligence tests, but is IQ just a cultural construct? ("Mismeasure of man" debate ...);
 - may just be a mathematical/computational device (e.g. in MCMC or EM algorithms).
- Examples include random effects models, use of hidden variables in probit regression, mixture models.

Galaxy data

APTS: Statistical Modelling

March 2011 – slide 164

Mixture density

- Natural model for such data is a p -component mixture density

$$f(y; \theta) = \sum_{r=1}^p \pi_r f_r(y; \theta), \quad 0 \leq \pi_r \leq 1, \quad \sum_{r=1}^p \pi_r = 1,$$

where π_r is the probability that Y comes from the r th component and $f_r(y; \theta)$ is its density conditional on this event.

- Can represent this using indicator variables U taking a value in $1, \dots, p$ with probabilities π_1, \dots, π_p and indicating from which component Y is drawn.
- Widely used class of models, often with number of components p unknown.
- Aside: such models are non-regular for likelihood inference:
 - non-identifiable under permutation of components;
 - setting $\pi_r = 0$ eliminates parameters of f_r ;
 - maximum of likelihood can be $+\infty$, achieved for several θ

APTS: Statistical Modelling

March 2011 – slide 165

Other latent variable models

- Let $[U], D$ denote discrete random variables, and $(U), X$ continuous ones. Then in notation for graphical models:
 - $[U] \rightarrow X$ or $[U] \rightarrow D$ denotes finite mixture models, hidden Markov models, changepoint models, etc.;
 - $(U) \rightarrow D$ denotes data coarsening (censoring, truncation, ...);
 - $(U) \rightarrow X$ or $(U) \rightarrow D$ denotes variance components and other hierarchical models.
- Binary regression: $U \sim \mathcal{N}(x^T \beta, 1)$ and observed response $Y = I(U \geq 0)$, gives probit regression model, log likelihood contribution

$$Y \log \Phi(x^T \beta) + (1 - Y) \log \{1 - \Phi(x^T \beta)\},$$

and similarly if different continuous distribution is chosen for U (logistic, extreme-value, ...).

APTS: Statistical Modelling

March 2011 – slide 166

EM algorithm

- Aim to use observed value y of Y for inference on θ when we cannot easily compute

$$f(y; \theta) = \int f(y | u; \theta) f(u; \theta) du$$

- The **complete-data log likelihood**

$$\log f(y, u; \theta) = \log f(y; \theta) + \log f(u | y; \theta), \quad (25)$$

is based on (U, Y) , whereas the **observed-data log likelihood** is

$$\ell(\theta) = \log f(y; \theta).$$

- Take expectation in (25) with respect to $f(u | y; \theta')$ to get

$$E \{ \log f(Y, U; \theta) | Y = y; \theta' \} = \ell(\theta) + E \{ \log f(U | Y; \theta) | Y = y; \theta' \}, \quad (26)$$

or equivalently $Q(\theta; \theta') = \ell(\theta) + C(\theta; \theta')$.

APTS: Statistical Modelling

March 2011 – slide 168

EM algorithm II

Fix θ' and consider how $Q(\theta; \theta')$ and $C(\theta; \theta')$ depend on θ .

- Note that $C(\theta'; \theta') \geq C(\theta; \theta')$, with equality only when $\theta = \theta'$ (Jensen's inequality).
- Thus

$$Q(\theta; \theta') \geq Q(\theta'; \theta') \text{ implies } \ell(\theta) - \ell(\theta') \geq C(\theta'; \theta') - C(\theta; \theta') \geq 0. \quad (27)$$

- Under mild smoothness conditions, $C(\theta; \theta')$ has a stationary point at $\theta = \theta'$, so if $Q(\theta; \theta')$ is stationary at $\theta = \theta'$, so too is $\ell(\theta)$.

- Hence **EM algorithm**: starting from an initial value θ' of θ ,

1. compute $Q(\theta; \theta') = E \{ \log f(Y, U; \theta) | Y = y; \theta' \}$; then
2. with θ' fixed, maximize $Q(\theta; \theta')$ over θ , giving θ^\dagger , say; and
3. check if the algorithm has converged, using $\ell(\theta^\dagger) - \ell(\theta')$ if available, or $|\theta^\dagger - \theta'|$, or both. If not, set $\theta' = \theta^\dagger$ and go to 1.

Steps 1 and 2 are the **expectation (E)** and **maximization (M)** steps.

- The M-step ensures that $Q(\theta^\dagger; \theta') \geq Q(\theta'; \theta')$, so (27) implies that $\ell(\theta^\dagger) \geq \ell(\theta')$: the log likelihood never decreases.

APTS: Statistical Modelling

March 2011 – slide 169

Convergence

- If $\ell(\theta)$ has
 - only one stationary point, and if $Q(\theta; \theta')$ eventually reaches a stationary value at $\hat{\theta}$, then $\hat{\theta}$ must maximize $\ell(\theta)$;
 - otherwise the algorithm may converge to a local maximum of the log likelihood or to a turning point.
- The EM algorithm never decreases the log likelihood so is more stable than Newton–Raphson-type algorithms.
- Rate of convergence depends on closeness of $Q(\theta; \theta')$ and $\ell(\theta)$:

$$-\frac{\partial^2 \ell(\theta)}{\partial \theta \partial \theta^T} = E \left\{ -\frac{\partial^2 \log f(y, U; \theta)}{\partial \theta \partial \theta^T} \middle| Y = y; \theta \right\} - E \left\{ -\frac{\partial^2 \log f(U | y; \theta)}{\partial \theta \partial \theta^T} \middle| Y = y; \theta \right\},$$

or $J(\theta) = I_c(\theta; y) - I_m(\theta; y)$, giving the **missing information principle**: the observed information equals the complete-data information minus the missing information.

- Rate of convergence slow if largest eigenvalue of $I_c(\theta; y)^{-1} I_m(\theta; y) \approx 1$; this occurs if the missing information is a high proportion of the total.

APTS: Statistical Modelling

March 2011 – slide 170

(Toy) Example: Negative binomial model

Conditional on $U = u$, $Y \sim \text{Pois}(u)$ and U is gamma with mean θ and variance θ^2/ν . Suppose $\nu > 0$ known and make inference for θ .

EM algorithm for negative binomial example. Left panel: observed-data log likelihood $\ell(\theta)$ (solid) and functions $Q(\theta; \theta')$ for $\theta' = 1.5, 1.347$ and 1.028 (dots, from right). The blobs show the values of θ that maximize these functions, which correspond to the first, fifth and fortieth iterations of the EM algorithm. Right: convergence of EM algorithm (dots) and Newton–Raphson algorithm (solid). The panel shows how successive EM iterations update θ' and $\hat{\theta}$. Notice that the EM iterates always increase $\ell(\theta)$, while the Newton–Raphson steps do not.

APTS: Statistical Modelling

March 2011 – slide 171

Example: Mixture model

- Consider earlier p -component mixture density $f(y; \theta) = \sum_{r=1}^p \pi_r f_r(y; \theta)$, for which likelihood contribution from (y, u) would be $\prod_r \{f_r(y; \theta) \pi_r\}^{I(u=r)}$, giving contribution

$$\log f(y, u; \theta) = \sum_{r=1}^p I(u = r) \{ \log \pi_r + \log f_r(y; \theta) \}$$

to the complete-data log likelihood.

- Must compute the expectation of $\log f(y, u; \theta)$ over

$$w_r(y; \theta') = \Pr(U = r \mid Y = y; \theta') = \frac{\pi_r' f_r(y; \theta')}{\sum_{s=1}^p \pi_s' f_s(y; \theta')}, \quad r = 1, \dots, p, \quad (28)$$

the weight attributable to component r if y has been observed.

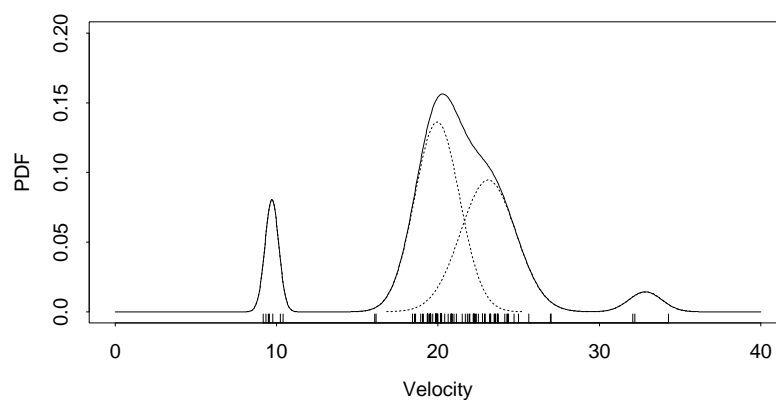

- The expected value of $I(U = r)$ with respect to (28) is $w_r(y; \theta')$, so the expected value of the log likelihood based on a random sample $(y_1, u_1), \dots, (y_n, u_n)$ is

$$\begin{aligned} Q(\theta; \theta') &= \sum_{j=1}^n \sum_{r=1}^p w_r(y_j; \theta') \{ \log \pi_r + \log f_r(y_j; \theta) \} \\ &= \sum_{r=1}^p \left\{ \sum_{j=1}^n w_r(y_j; \theta') \right\} \log \pi_r + \sum_{r=1}^p \sum_{j=1}^n w_r(y_j; \theta') \log f_r(y_j; \theta). \end{aligned}$$

Example: Galaxy data

p	1	2	3	4	5
$\hat{\ell}$	-240.42	-220.19	-203.48	-202.52	-192.42

Fitted mixture model with $p = 4$ normal components:

Galaxy data

AIC and BIC for the normal mixture models fitted to the galaxy data. BIC is minimised for $p = 3$ components, and AIC for $p = 5$ components.

APTS: Statistical Modelling

March 2011 – slide 174

Exponential family

- Suppose the complete-data log likelihood is from an exponential family:

$$\log f(y, u; \theta) = s(y, u)^T \theta - \kappa(\theta) + c(y, u).$$

- For EM algorithm, need expected value of $\log f(y, u; \theta)$ with respect to $f(u | y; \theta')$. Final term can be ignored, so M-step involves maximizing

$$Q(\theta; \theta') = E \{s(y, U)^T \theta | Y = y; \theta'\} - \kappa(\theta),$$

or equivalently solving for θ the equation

$$E \{s(y, U) | Y = y; \theta'\} = \frac{d\kappa(\theta)}{d\theta}.$$

- Likelihood equation for θ based on the complete data is $s(y, u) = d\kappa(\theta)/d\theta$, so the EM algorithm replaces $s(y, u)$ by its conditional expectation $E \{s(y, U) | Y = y; \theta'\}$ and solves the likelihood equation. Thus a routine to fit the complete-data model can readily be adapted for missing data if the conditional expectations are available.

APTS: Statistical Modelling

March 2011 – slide 175

Comments

- Often E-step requires numerical approximation:
 - simulation from conditional distribution of U given Y ;
 - importance sampling;
 - Markov chain algorithm;
- M-step can be performed using Newton–Raphson or similar algorithm, using first and second loglikelihood derivatives (exercise)—may need to be performed in parts, rather than overall
- Can obtain standard errors using these derivatives (exercise)
- In Bayesian analysis, may often be helpful to include latent variables, either
 - because they have useful interpretation in terms of model—*all* parameters are hidden variables, because unobservable in practice
 - to simplify MCMC algorithm—Gibbs sampler is 'Bayesian equivalent' of EM algorithm (exercise)
